Collateral Circulation.—After ligature of the third part of the subclavian artery the collateral circulation is mainly established by three sets of vessels, thus described in a dissection:

"1. A posterior set, consisting of the suprascapular and posterior scapular branches of the subclavian, anastomosing with the median branch from the subscapular from the axillary.

"2. An internal set produced by the connection of the internal mammary on the one hand,

¹ The operation was, however, performed in New York by Dr. J. K. Rodgers, and the case is related in *A System of Surgery*, edited by T. Holmes, 2d ed. vol. iii. pp. 629, etc.

with the superior and long thoracic arteries, and the branches from the subscapular on the other.

"3. A middle or axillary set, which consisted of a number of small vessels derived from branches of the subclavian, above, and, passing through the axilla, terminated either in the main trunk or some of the branches of the axillary below. This last set presented most conspicuously the peculiar character of newly-formed or, rather, dilated arteries, being excessively tortuous, and forming a complete plexus.

"The chief agent in the restoration of the axillary artery below the tumor was the subscapular artery, which communicated most freely with the internal mammary, suprascapular, and posterior scapular branches of the subclavian, from all of which it received so great an influx of blood as to dilate it to three times its natural size."¹

When a ligature is applied to the first part of the subclavian artery, the collateral circulation is carried on by—1, the anastomosis between the superior and inferior thyroid; 2, the anastomosis of the two vertebrals; 3, the anastomosis of the internal mammary with the deep epigastric and the aortic intercostals; 4, the superior intercostal anastomosing with the aortic intercostals; 5, the profunda cervicis anastomosing with the princeps cervicis; 6, the scapular branches of the thyroid axis anastomosing with the branches of the axillary; and 7, the thoracic branches of the axillary anastomosing with the aortic intercostals.

BRANCHES OF THE SUBCLAVIAN ARTERY.

These are four in number. On the left side all four branches, the *vertebral*, the *internal mammary*, the *thyroid axis*, and the *superior intercostal*, generally arise from the first portion of the vessel; but on the right side the superior intercostal usually arises from the second portion of the vessel. On both sides of the body the first three branches arise close together at the inner margin of the *Scalenus anticus*, in the majority of cases a free interval of half an inch to an inch existing between the commencement of the artery and the origin of the nearest branch; in a smaller number of cases an interval of more than an inch exists, never exceeding an inch and three-quarters. In a very few instances the interval had been found to be less than half an inch.

The **Vertebral Artery** (Fig. 352) is generally the first and largest branch of the subclavian; it arises from the upper and back part of the first portion of the vessel, and, passing upward, enters the foramen in the transverse process of the sixth cervical vertebra,² and ascends through the foramina in the transverse processes of all the vertebræ above this. Above the upper border of the axis it inclines outward and upward to the foramen in the transverse process of the atlas, through which it passes; it then winds backward behind its articular process, runs in a deep groove on the upper surface of the posterior arch of this bone, and, passing beneath the posterior occipito-atlantal ligament, pierces the dura mater and enters the skull through the foramen magnum. It then passes forward and upward to the front of the medulla oblongata, and unites with the vessel of the opposite side at the lower border of the pons Varolii to form the *basilar artery*.

Relations.—At its origin it is situated behind the internal jugular vein and inferior thyroid artery and near the spine; it lies between the *Longus colli* and *Scalenus anticus* muscles, having the thoracic duct in front of it on the left side. Within the foramina formed by the transverse processes of the vertebræ it is accompanied by a plexus of nerves from the inferior cervical ganglion of the sympathetic, and is surrounded by a dense plexus of veins which unite to form the

FIG. 360.—Plan of the branches of the right subclavian artery.

¹ *Guy's Hospital Reports*, vol. i. 1836: case of axillary aneurism, in which Mr. Aston Key had tied the subclavian artery on the outer edge of the *Scalenus* muscle twelve years previously.

² The vertebral artery sometimes enters the foramen in the transverse process of the fifth vertebra. Dr. Smyth, who tied this artery in the living subject, found it, in one of his dissections, passing into the foramen in the seventh vertebra.

vertebral vein at the lower part of the neck. It is situated in front of the cervical nerves as they issue from the intervertebral foramina. Whilst winding round the articular process of the atlas it is contained in a triangular space (*suboccipital triangle*) formed by the Rectus capitis posterior major, the Superior and the Inferior oblique muscles; and at this point is covered by the Complexus muscle. Within the skull, as it winds round the medulla oblongata, it is placed between the hypoglossal nerve and the anterior root of the suboccipital nerve, beneath the first digitation of the ligamentum denticulatum, and finally lies between the dura mater covering the basilar process of the occipital bone and the anterior surface of the medulla oblongata.

Branches.—These may be divided into two sets—those given off in the neck and those within the cranium.

Cervical Branches.

Lateral Spinal.
Muscular.

Cranial Branches.

Posterior Meningeal.
Anterior Spinal.
Posterior Spinal.
Posterior Inferior Cerebellar.

The **lateral spinal branches** enter the spinal canal through the intervertebral foramina and divide into two branches. Of these, one passes along the roots of the nerves to supply the spinal cord and its membranes, anastomosing with the other arteries of the spinal cord; the other divides into an ascending and a descending branch, which unite with similar branches from the artery above and below, so that two lateral anastomotic chains are formed on the posterior surface of the bodies of the vertebrae near the attachment of the pedicles. From these anastomotic chains branches are given off to supply the periosteum and the bodies of the vertebrae, and to communicate with similar branches from the opposite side; from these latter small branches are given off which join similar branches above and below, so that a central anastomotic chain is formed on the posterior surface of the bodies of the vertebrae.

Muscular branches are given off to the deep muscles of the neck, where the vertebral artery curves round the articular process of the atlas. They anastomose with the occipital and with the ascending and deep cervical arteries.

The **posterior meningeal** are one or two small branches given off from the vertebral opposite the foramen magnum. They ramify between the bone and dura mater in the cerebellar fossae, and supply the falx cerebelli.

The **anterior spinal** is a small branch, though larger than the posterior spinal, which arises near the termination of the vertebral, and, descending in front of the medulla oblongata, unites with its fellow of the opposite side at about the level of the foramen magnum. The single trunk, thus formed, descends on the front of the spinal cord, and is reinforced by a succession of small branches which enter the spinal canal through the intervertebral foramina; these branches are derived from the vertebral and ascending cervical of the inferior thyroid in the neck; from the intercostal in the dorsal region; and from the lumbar, ilio-lumbar, and lateral sacral arteries in the lower part of the spine. They unite, by means of ascending and descending branches, to form a single anterior median artery, which extends as far as the lower part of the spinal cord. This vessel is placed in the pia mater along the anterior median fissure: it supplies that membrane and the substance of the cord, and sends off branches at its lower part to be distributed to the cauda equina, and ends on the central fibrous prolongation of the cord.

The **posterior spinal** arises from the vertebral at the side of the medulla oblongata: passing backward to the posterior aspect of the spinal cord, it descends on each side, lying behind the posterior roots of the spinal nerves, and is reinforced by a succession of small branches which enter the spinal canal through the intervertebral foramina, and by which it is continued to the lower part of the

cord and to the cauda equina. Branches from these vessels form a free anastomosis round the posterior roots of the spinal nerves, and communicate, by means of very tortuous transverse branches, with the vessel of the opposite side. At its commencement it gives off an ascending branch, which terminates on the side of the fourth ventricle.

The **posterior inferior cerebellar artery** (Fig. 354), the largest branch of the vertebral, winds backward round the upper part of the medulla oblongata, passing between the origin of the pneumogastric and spinal accessory nerves, over the restiform body to the under surface of the cerebellum, where it divides into two branches—an internal one, which is continued backward to the notch between the two hemispheres of the cerebellum; and an external one, which supplies the under surface of the cerebellum as far as its outer border, where it anastomoses with the anterior inferior cerebellar and the superior cerebellar branches of the basilar artery. Branches from this artery supply the choroid plexus of the fourth ventricle.

Surgical Anatomy.—The vertebral artery has been tied in several instances: 1. for wounds or traumatic aneurism; 2. after ligature of the innominate, either at the same time to prevent hæmorrhage, or later on to arrest bleeding where it has occurred at the seat of ligature; and 3. in epilepsy. In these latter cases the treatment has been recommended by Dr. Alexander of Liverpool, in the hope that by diminishing the supply of blood to the posterior part of the brain and the spinal cord a diminution or cessation of the epileptic fits would result. The operation of ligature of the vertebral is performed by making an incision along the posterior border of the Sterno-mastoid muscle, just above the clavicle. The muscle is pulled to the inner side, and the anterior tubercle of the transverse process of the sixth cervical vertebra sought for. A deep layer of fascia being now divided, the interval between the *Scalenus anticus* and the *Longus colli* just below their insertion into the tubercle is defined, and the artery and vein found in the interspace. The vein is to be drawn to the outer side, and the aneurism needle passed from without inward. Drs. Ramskill and Bright have pointed out that severe pain at the back of the head may be symptomatic of disease of the vertebral artery just before it enters the skull. This is explained by the close connection of the artery with the sub-occipital nerve in the groove on the posterior arch of the atlas. Disease of the same artery has been also said to affect speech, from pressure on the hypoglossal where it is in relation with the vessel, leading to paralysis of the muscles of the tongue.

The **Basilar Artery**, so named from its position at the base of the skull, is a single trunk formed by the junction of the two vertebral arteries; it extends from the posterior to the anterior border of the pons Varolii, lying in its median groove, under cover of the arachnoid. It ends by dividing into two branches, the *posterior cerebral arteries*. Its branches are, on each side, the following:

Transverse.	Superior Cerebellar.
Anterior Inferior Cerebellar.	Posterior Cerebral.

The **transverse branches** supply the pons Varolii and adjacent parts of the brain, one branch, the *internal auditory*, accompanies the auditory nerve into the internal auditory meatus; and another, the *anterior inferior cerebellar artery*, passes across the crus cerebelli, to be distributed to the anterior border of the under surface of the cerebellum.

The **superior cerebellar arteries** arise near the termination of the basilar. They wind round the crus cerebri close to the fourth nerve, and, arriving at the upper surface of the cerebellum, divide into branches which ramify in the pia mater and anastomose with the branches of the inferior cerebellar artery. Several branches are given to the pineal gland and also to the velum interpositum.

The **posterior cerebral arteries**, the two terminal branches of the basilar, are larger than the preceding, from which they are separated near their origin by the third nerves. Winding round the crus cerebri, they pass to the under surface of the occipital lobes of the cerebrum and divide into three main branches. Near their origin they receive the posterior communicating arteries from the internal carotid. The branches of the posterior cerebral artery are—

Postero-median Ganglionic.	Postero-lateral Ganglionic.
Posterior Choroid.	Three Terminal.

The *postero-median ganglionic branches* (Fig. 357) are a group of small arteries which arise at the commencement of the posterior cerebral artery; these, with similar branches from the posterior communicating, pierce the posterior perforated space and supply the internal surfaces of the optic thalami and the walls of the third ventricle. The *posterior choroid* enters the interior of the brain beneath the posterior border of the corpus callosum and supplies the velum interpositum and the choroid plexus. The *postero-lateral ganglionic branches* are a group of small arteries which arise from the posterior cerebral artery after it has turned round the crus cerebri; they supply a considerable portion of the optic thalamus. The *terminal branches* are distributed as follows: the first to the uncinate gyrus; the second to the temporo-sphenoidal lobe; and the third to the cuneus or the occipital lobule.

Circle of Willis.—The remarkable anastomosis which exists between the branches of the internal carotid and vertebral arteries at the base of the brain constitutes the *circle of Willis*. It is formed, in front, by the anterior cerebral arteries, branches of the internal carotid, which are connected together by the anterior communicating; behind, by the two posterior cerebrals, branches of the basilar, which are connected on each side with the internal carotid by the posterior communicating arteries (Fig. 354). It is by this anastomosis that the cerebral circulation is equalized, and provision made for effectually carrying it on if one or more of the branches are obliterated. The parts of the brain included within this arterial circle are—the lamina cinerea, the commissure of the optic nerves, the infundibulum, the tuber cinereum, the corpora albicantia, and the posterior perforated space.

The **Thyroid Axis** (Fig. 347) is a short thick trunk which arises from the fore part of the first portion of the subclavian artery, close to the inner border of the Scalenus anticus muscle, and divides, almost immediately after its origin, into three branches—the *inferior thyroid*, *suprascapular*, and *transversalis colli*.

The **Inferior Thyroid Artery** passes upward, in a serpentine course, behind the sheath of the common carotid vessel and sympathetic nerve (the middle cervical ganglion resting upon it), and in front of the vertebral artery, recurrent laryngeal nerve, and Longus colli muscle, and is distributed to the under surface of the thyroid gland, anastomosing with the superior thyroid and with the corresponding artery of the opposite side. Its branches are—the

Inferior Laryngeal.	Œsophageal.
Tracheal.	Ascending Cervical.
Muscular.	

The **inferior laryngeal branch** ascends upon the trachea to the back part of the larynx, in company with the recurrent laryngeal nerve, and supplies the muscles and mucous membrane of this part, anastomosing with the branch from the opposite side and with the laryngeal branch from the superior thyroid artery.

The **tracheal branches** are distributed upon the trachea, anastomosing below with the bronchial arteries.

The **œsophageal branches** are distributed to the œsophagus, and anastomose with the œsophageal branches of the aorta.

The **ascending cervical** is a small branch which arises from the inferior thyroid just where that vessel is passing behind the common carotid artery, and runs up on the anterior tubercles of the transverse processes of the cervical vertebræ in the interval between the Scalenus anticus and Rectus capitis anticus major. It gives branches to the muscles of the neck, which anastomose with branches of the vertebral, and sends one or two branches into the spinal canal through the intervertebral foramina to be distributed to the spinal cord and its membranes, and to the bodies of the vertebræ in the same manner as the lateral spinal branches from the vertebral. It anastomoses with the ascending pharyngeal artery.

The **muscular branches** supply the depressors of the hyoid bone, the Longus colli, the Scalenus anticus, and the Inferior constrictor of the pharynx.

Surgical Anatomy.—This artery is sometimes tied, in conjunction with the superior thyroid, in cases of bronchocele. An incision is made along the anterior border of the Sternomastoid down to the clavicle. After the deep fascia has been divided, the Sternomastoid and carotid vessels are drawn outward and the carotid (Chassaignac's) tubercle sought for. The vessel will be found just below this tubercle, between the carotid sheath on the outer side of the trachea and oesophagus on the inner side. In passing the ligature great care must be exercised to avoid including the recurrent laryngeal nerve.

The **Suprascapular Artery** (*transversalis humeri*), smaller than the *transversalis colli*, passes obliquely from within outward, across the root of the neck. It at first lies on the lower part of the *Scalenus anticus*, being covered by the Sternomastoid; it then crosses the subclavian artery, and runs outward behind and parallel with the clavicle and Subclavius muscle, and beneath the posterior belly of the Omo-hyoid, to the superior border of the scapula, where it passes over the transverse ligament of the scapula to the supraspinous fossa. In this situation it lies close to the bone, and ramifies between it and the Supraspinatus muscle, to which it is mainly distributed, giving off a communicating branch which crosses

FIG. 36L.—The scapular and circumflex arteries.

the neck of the scapula, to reach the infraspinous fossa, where it anastomoses with the dorsal branch of the subscapular artery. Besides distributing branches to the Sternomastoid and neighboring muscles, it gives off a *supra-acromial branch*, which, piercing the Trapezius muscle, supplies the cutaneous surface of the acromion, anastomosing with the acromial thoracic artery. As the artery passes over the transverse ligament of the scapula a branch descends into the subscapular fossa, ramifies beneath that muscle, and anastomoses with the posterior and subscapular arteries. It also supplies the shoulder-joint and a nutrient branch to the clavicle.

The **Transversalis Colli** passes transversely outward, across the upper part of the subclavian triangle, to the anterior margin of the Trapezius muscle, beneath which it divides into two branches, the *superficial cervical* and the *posterior scapular*. In its passage across the neck it crosses in front of the *Scaleni* muscles and the brachial plexus, between the divisions of which it sometimes passes, and is covered by the Platysma, Sternomastoid, Omo-hyoid, and Trapezius muscles.

The **superficial cervical** ascends beneath the anterior margin of the Trapezius, distributing branches to it and to the neighboring muscles and glands in the neck, and anastomoses with the superficial branch of the *arteria princeps cervicis*.

The **posterior scapular**, the continuation of the *transversalis colli*, passes

beneath the Levator anguli scapulæ to the superior angles of the scapula. It now descends along the posterior border of that bone as far as the inferior angle, where it anastomoses with the subscapular branch of the axillary. In its course it is covered by the Rhomboid muscles, supplying them and the Latissimus dorsi and Trapezius, and anastomosing with the suprascapular and subscapular arteries and with the posterior branches of some of the intercostal arteries.

Peculiarities.—The *superficial cervical* frequently arises as a separate branch from the thyroid axis; and the posterior scapular, from the third, more rarely from the second, part of the subclavian.

The **Internal Mammary** arises from the under surface of the first portion of the subclavian artery, opposite the thyroid axis. It descends behind the costal cartilage of the first rib to the inner surface of the anterior wall of the chest, resting against the costal cartilages about half an inch from the margin of the sternum; and at the interval between the sixth and seventh cartilages divides into two branches, the *musculo-phrenic* and *superior epigastric*.

Relations.—At its origin it is covered by the internal jugular and subclavian veins and crossed by the phrenic nerve. In the upper part of the thorax it lies against the costal cartilages and Internal intercostal muscles in front, and is covered by the pleura behind. At the lower part of the thorax the Triangularis sterni separates the artery from the pleura.

The branches of the internal mammary are—

Comes Nervi Phrenici (Superior Phrenic).	Anterior Intercostal.
Mediastinal.	Perforating.
Pericardiac.	Musculo-phrenic.
Sternal.	Superior Epigastric.

The **comes nervi phrenici (superior phrenic)**, is a long slender branch which accompanies the phrenic nerve, between the pleura and pericardium, to the Diaphragm, to which it is distributed, anastomosing with the other phrenic arteries from the internal mammary and abdominal aorta.

The **mediastinal branches** are small vessels which are distributed to the areolar tissue and lymphatic glands in the anterior mediastinum and the remains of the thymus gland.

The **pericardiac branches** supply the upper part of the anterior surface of the pericardium, the lower part receiving branches from the musculo-phrenic artery.

The **sternal branches** are distributed to the Triangularis sterni and to the posterior surface of the sternum.

The mediastinal, pericardiac, and sternal branches, together with some twigs from the comes nervi phrenici, anastomose with branches from the intercostal and bronchial arteries, and form a minute plexus beneath the pleura, which has been named by Turner the *subpleural mediastinal plexus*.

The **anterior intercostal arteries** supply the five or six upper intercostal spaces. The branch corresponding to each space soon divides into two, or the two branches may come off separately from the parent trunk. The small vessels pass outward in the intercostal spaces, one lying near the lower margin of the rib above, and the other near the upper margin of the rib below, and anastomose with the intercostal arteries from the aorta. They are at first situated between the pleura and the Internal intercostal muscles, and then between the Internal and External intercostal muscles. They supply the Intercostal muscles, and, by branches which perforate the External intercostal muscle, the Pectoral muscles and the mammary gland.

The **perforating arteries** correspond to the five or six upper intercostal spaces. They arise from the internal mammary, pass forward through the intercostal spaces, and, curving outward, supply the Pectoralis major and the integument. Those which correspond to the second, third, and fourth spaces are distributed to the mammary gland. In females, during lactation, these branches are of large size.

The **musculo-phrenic artery** is directed obliquely downward and outward,

behind the cartilages of the false ribs, perforating the Diaphragm at the eighth or ninth rib, and terminating, considerably reduced in size, opposite the last intercostal space. It gives off anterior intercostal arteries to each of the intercostal spaces across which it passes; these diminish in size as the spaces decrease in length, and are distributed in a manner precisely similar to the anterior intercostals from the internal mammary. The musculo-phrenic also gives branches to the lower part of the pericardium, and others which run backward to the Diaphragm and downward to the abdominal muscles.

The **superior epigastric** continues in the original direction of the internal mammary; it descends through the cellular interval between the costal and sternal attachments of the Diaphragm, and enters the sheath of the Rectus abdominis muscle, at first lying behind the muscle, and then perforating it and supplying it, and anastomosing with the deep epigastric artery from the external iliac. Some vessels perforate the sheath of the Rectus, and supply the muscles of the abdomen and the integument, and a small branch, which passes inward upon the side of the ensiform appendix, anastomoses in front of that cartilage with the artery of the opposite side.

Surgical Anatomy.—The course of the internal mammary artery may be defined by drawing a line across the six upper intercostal spaces half an inch from and parallel with the sternum. The position of the vessel must be remembered, as it is liable to be wounded in stabs of the chest-wall. It is most easily reached by a transverse incision in the second intercostal space.

The **Superior Intercostal** (Fig. 352) arises from the upper and back part of the subclavian artery, behind the Anterior scalenus on the right side, and to the inner side of the muscle on the left side. Passing backward, it gives off the *deep cervical branch*, and then descends behind the pleura in front of the necks of the first two ribs, and inosculates with the first aortic intercostal.¹ In the first intercostal space it gives off a branch which is distributed in a manner similar to the distribution of the aortic intercostals. The branch for the second intercostal space usually joins with one from the aortic intercostals. Each intercostal gives off a branch to the posterior spinal muscles, and a small one which passes through the corresponding intervertebral foramen to the spinal cord and its membranes.

The **deep cervical branch** (*profunda cervicis*) arises, in most cases, from the superior intercostal, and is analogous to the posterior branch of an aortic intercostal artery. Passing backward, between the transverse process of the seventh cervical vertebra and the first rib, it runs up the back part of the neck, between the Complexus and Semispinalis colli muscles, as high as the axis, supplying these and adjacent muscles, and anastomosing with the deep branch of the *arteria princeps cervicis* of the occipital and with branches which pass outward from the vertebral.

SURGICAL ANATOMY OF THE AXILLA.

The **Axilla** is a pyramidal space, situated between the upper and lateral part of the chest and the inner side of the arm.

Boundaries.—Its *apex*, which is directed upward toward the root of the neck, corresponds to the interval between the first rib, the upper edge of the scapula, and the clavicle, through which the axillary vessels and nerves pass. The *base*, directed downward, is formed by the integument, and a thick layer of fascia extending between the lower border of the Pectoralis major in front, and the lower border of the Latissimus dorsi behind; it is broad internally at the chest, but narrow and pointed externally at the arm. The *anterior boundary* is formed by the Pectoralis major and minor muscles, the former covering the whole of the anterior wall of the axilla, the latter covering only its central part. The *posterior boundary*, which extends somewhat lower than the anterior, is formed by the Subscapularis above, the Teres major and Latissimus dorsi below. On the *inner side* are the first four ribs with their corresponding Intercostal muscles, and part of the Serratus magnus. On the *outer side*, where the anterior and posterior boundaries

¹ See foot-note, p. 609.

converge, the space is narrow, and bounded by the humerus, the Coraco-brachialis and Biceps muscles.

Contents.—This space contains the axillary vessels and brachial plexus of nerves, with their branches, some branches of the intercostal nerves, and a large number of lymphatic glands, all connected together by a quantity of fat and loose areolar tissue.

Their Position.—The axillary artery and vein, with the brachial plexus of nerves, extend obliquely along the outer boundary of the axillary space, from its apex to its base, and are placed much nearer the anterior than the posterior wall, the vein lying to the inner or thoracic side of the artery and partially concealing it. At the fore part of the axillary space, in contact with the Pectoral muscles, are the thoracic branches of the axillary artery, and along the anterior margin

FIG. 362.—The axillary artery and its branches.

of the axilla the long thoracic artery extends to the side of the chest. At the back part, in contact with the lower margin of the Subscapularis muscle, are the subscapular vessels and nerves; winding around the lower border of this muscle is the dorsalis scapulæ artery and veins; and toward the outer extremity of the muscle the posterior circumflex vessels and the circumflex nerve are seen curving backward to the shoulder.

Along the inner or thoracic side no vessel of any importance exists, the upper part of the space being crossed merely by a few small branches from the superior thoracic artery. There are some important nerves, however, in this situation—viz. the posterior thoracic or external respiratory nerve, descending on the surface of the Serratus magnus, to which it is distributed; and perforating the upper and anterior part of this wall, the intercosto-humeral nerve or nerves, passing across the axilla to the inner side of the arm.

The cavity of the axilla is filled by a quantity of loose areolar tissue and a large number of small arteries and veins, all of which are, however, of inconsiderable

size, and numerous lymphatic glands: these are from ten to twelve in number, and situated chiefly on the thoracic side and lower and back part of this space.

Surgical Anatomy.—The axilla is a space of considerable surgical importance. It transmits the large vessels and nerves to the upper extremity, and these may be the seat of injury or disease: it contains numerous lymphatic glands which may require removal when diseased; in it is a quantity of loose connective and adipose tissue which may be readily infiltrated with blood or inflammatory exudation, and it may be the seat of rapidly-growing tumors. Moreover, it is covered at its base by thin skin, largely supplied with sebaceous and sweat glands, which is frequently the seat of small cutaneous abscesses and boils, and of eruptions due to irritation.

In suppuration in the axilla the arrangement of the fasciæ plays a very important part in the direction which the pus takes. As described on page 470, the costo-coracoid membrane, after covering in the space between the clavicle and the upper border of the Pectoralis minor, splits to enclose this muscle, and, reblending at its lower border, becomes incorporated with the fascia covering the Pectoralis major muscle at the anterior fold of the axilla. This is known as the clavi-pectoral fascia. Suppuration may take place either superficial to or beneath this layer of fascia; that is, either between the pectorals or below the pectoralis minor: in the former case, it would point either at the anterior border of the axillary fold or in the groove between the Deltoid and the Pectoralis major; in the latter, the pus would have a tendency to surround the vessels and nerves and ascend into the neck, that being the direction in which there is least resistance. Its progress toward the skin is prevented by the axillary fascia; its progress backward, by the Serratus magnus; forward, by the clavi-pectoral fascia; inward, by the wall of the thorax; and outward, by the upper limb. The pus in these cases, after extending into the neck, has been known to spread through the superior opening of the thorax into the mediastinum.

In opening an axillary abscess the knife should be entered in the floor of the axilla, midway between the anterior and posterior margins and near the thoracic side of the space. It is well to use a director and dressing forceps after an incision has been made through the skin and fascia in the manner directed by the late Mr. Hilton.

The student should attentively consider the relation of the vessels and nerves in the several parts of the axilla, for it not unfrequently happens that the surgeon is called upon to extirpate diseased glands or to remove a tumor from this situation. In performing such an operation it will be necessary to proceed with much caution in the direction of the outer wall and apex of the space, as here the axillary vessels will be in danger of being wounded. Toward the posterior wall it will be necessary to avoid the subscapular, dorsalis scapulae, and posterior circumflex vessels. Along the anterior wall it will be necessary to avoid the thoracic branches. It is only along the inner or thoracic wall, and in the centre of the axillary cavity, that there are no vessels of any importance—a fortunate circumstance, for it is in this situation more especially that tumors requiring removal are usually situated.

THE AXILLARY ARTERY.

The **Axillary Artery**, the continuation of the subclavian, commences at the lower border of the first rib, and terminates at the lower border of the tendon of the Teres major muscle, where it takes the name of brachial. Its direction varies with the position of the limb: when the arm lies by the side of the chest, the vessel forms a gentle curve, the convexity being upward and outward; when it is directed at right angles with the trunk, the vessel is nearly straight; and when it is elevated still higher, the artery describes a curve the concavity of which is directed upward. At its commencement the artery is very deeply situated, but near its termination is superficial, being covered only by the skin and fascia. The description of the relations of this vessel is facilitated by its division into three portions, the first portion being that above the Pectoralis minor; the second portion, behind; and the third below, that muscle.

The **first portion of the axillary artery** is in relation, *in front*, with the clavicular portion of the Pectoralis major, the costo-coracoid membrane, the external anterior thoracic nerve, and the acromio-thoracic and cephalic veins; *behind*, with the first intercostal space, the corresponding Intercostal muscle, the second and third serrations of the Serratus magnus, and the posterior thoracic nerve; on its *outer side*, with the brachial plexus, from which it is separated by a little cellular interval; on its *inner* or thoracic side, with the axillary vein.

RELATIONS OF THE FIRST PORTION OF THE AXILLARY ARTERY.

In front.

Pectoralis major.
Costo-coracoid membrane.
External anterior thoracic nerve.
Acromio-thoracic and Cephalic veins.

Outer side.
Brachial plexus.

Inner side.
Axillary vein.

Behind.

First Intercostal space, and Intercostal muscle.
Second and third serrations of Serratus magnus.
Posterior thoracic nerve.

The **second portion of the axillary artery** lies behind the Pectoralis minor. It is covered, *in front*, by the Pectoralis major and minor muscles; *behind*, it is separated from the Subscapularis by a cellular interval; on the *inner side* is the axillary vein. The brachial plexus of nerves surrounds the artery, and separates it from direct contact with the vein and adjacent muscles.

RELATIONS OF THE SECOND PORTION OF THE AXILLARY ARTERY.

In front.

Pectoralis major and minor.

Outer side.
Outer cord of plexus.

Inner side.
Axillary vein.
Inner cord of plexus.

Behind.

Subscapularis.
Posterior cord of plexus.

The **third portion of the axillary artery** lies below the Pectoralis minor. It is in relation, *in front*, with the lower part of the Pectoralis major above, being covered only by the integument and fascia below, where it is crossed by the inner head of the median nerve; *behind*, with the lower part of the Subscapularis and the tendons of the Latissimus dorsi and Teres major; on its *outer side*, with the Coraco-brachialis; on its *inner* or thoracic side, with the axillary vein. The nerves of the brachial plexus bear the following relation to the artery in this part of its course: on the *outer side* is the median nerve, and the musculo-cutaneous for a short distance; on the *inner side*, the ulnar, the internal, and lesser internal cutaneous nerves; and *behind*, the musculo-spiral and circumflex, the latter extending only to the lower border of the Subscapularis muscle.

Peculiarities.—The axillary artery, in about one case out of every ten, gives off a large branch, which forms either one of the arteries of the forearm or a large muscular trunk. In the first set of cases this artery is most frequently the radial (1 in 23), sometimes the ulnar (1 in 72), and, very rarely, the interosseous (1 in 506). In the second set of cases the trunk has been found to give origin to the subscapular, circumflex, and profunda arteries of the arm. Sometimes only one of the circumflex, or one of the profunda arteries, arose from the trunk. In these cases the brachial plexus surrounded the trunk of the branches, and not the main vessel.

RELATIONS OF THE THIRD PORTION OF THE AXILLARY ARTERY.

Musculo-spiral and circumflex nerves.

Surface Marking.—The course of the axillary artery may be marked out by raising the arm to a right angle and drawing a line from the middle of the clavicle to the point where the tendon of the Pectoralis major crosses the prominence caused by the Coraco-brachialis as it emerges from under cover of the anterior fold of the axilla. The third portion of the artery can be felt pulsating beneath the skin and fascia, at the junction of the anterior with the middle third of the space between the anterior and posterior folds of the axilla, close to the inner border of the Coraco-brachialis.

Surgical Anatomy.—The student, having carefully examined the relations of the axillary artery in its various parts, should now consider in what situation compression of this vessel may be most easily effected, and the best position for the application of a ligature to it when necessary.

Compression of the vessel may be required in the removal of tumors or in amputation of the upper part of the arm; and the only situation in which this can be effectually made is in the lower part of its course; by pressing on it in this situation from within outward against the humerus the circulation may be effectually arrested.

The axillary artery is perhaps more frequently lacerated than any other artery in the body, with the exception of the popliteal, by violent movements of the upper extremity, especially in those cases where its coats are diseased. It has occasionally been ruptured in attempts to reduce old dislocations of the shoulder-joint. This lesion is most likely to occur during the preliminary breaking down of adhesions, in consequence of the artery having contracted adhesions to the capsule of the joint. Aneurism of the axillary artery is of frequent occurrence, a large percentage of the cases being traumatic in their origin, due to the violence to which it is exposed in the varied, extensive, and often violent movement of the limb.

The application of a ligature to the axillary artery may be required in cases of aneurism of the upper part of the brachial or as a distal operation for aneurism of the subclavian; and there are only two situations in which it can be secured—viz. in the first and in the third parts of its course; for the axillary artery at its central part is so deeply seated, and, at the same time, so closely surrounded with large nervous trunks, that the application of a ligature to it in that situation would be almost impracticable.

In the **third part** of its course the operation is most simple, and may be performed in the following manner: The patient being placed on a bed and the arm separated from the side, with the hand supinated, an incision is made through the integument forming the floor of the axilla about two inches in length, a little nearer to the anterior than the posterior fold of the axilla. After carefully dissecting through the areolar tissue and fascia, the median nerve and axillary vein are exposed; the former having been displaced to the outer and the latter to the inner side of the arm, the elbow being at the same time bent, so as to relax the structures and facilitate their separation, the ligature may be passed round the artery from the ulnar to the radial side. This portion of the artery is occasionally crossed by a muscular slip derived from the Latissimus dorsi, which may mislead the surgeon during an operation. The occasional existence of this muscular fasciculus was spoken of in the description of the muscles. It may easily be recognized by the transverse direction of its fibres.

The **first portion** of the axillary artery may be tied in cases of aneurism encroaching so far upward that a ligature cannot be applied in the lower part of its course. Notwithstanding that this operation has been performed in some few cases, and with success, its performance is attended with much difficulty and danger. The student will remark that in this situation it would be necessary to divide a thick muscle, and, after separating the costo-coracoid membrane, the artery would be exposed at the bottom of a more or less deep space, with the cephalic and axillary veins in such relation with it as must render the application of a ligature to this part of the vessel particularly hazardous. Under such circumstances it is an easier, and at the same time more advisable, operation to tie the subclavian artery in the third part of its course.

The vessel can be best secured by a curved incision with the convexity downward from a point half an inch external to the Sterno-clavicular joint to a point half an inch internal to the coracoid process. The limb is to be well abducted and the head inclined to the opposite side, and this incision carried through the superficial structures, care being taken of the cephalic vein at the outer angle of the incision. The clavicular origin of the Pectoralis major is then divided in the whole extent of the wound. The arm is now to be brought to the side, and the upper edge of the Pectoralis minor defined and drawn downward. The costo-coracoid membrane is to be carefully torn through with a director close to the coracoid process, and the axillary sheath exposed; this is to be opened with especial care on account of the vein overlapping the artery. The needle should be passed from below, so as to avoid wounding the vein.

In a case of wound of the vessel the general practice of cutting down upon, and tying it above and below the wounded point should be adopted in all cases.

Collateral Circulation after Ligature of the Axillary Artery.—If the artery be tied above the origin of the acromial thoracic, the collateral circulation will be carried on by the same branches as after the ligature of the subclavian; if at a lower point, between the acromial thoracic and subscapular arteries, the latter vessel, by its free anastomoses with the other scapular arteries, branches of the subclavian, will become the chief agent in carrying on the circulation, to which the long thoracic, if it be below the ligature, will materially contribute by its anastomoses with the intercostal and internal mammary arteries. If the point included in the ligature be below the origin of the subscapular artery, it will most probably also be below the origins of the two circumflex arteries. The chief agents in restoring the circulation will then be

the subscapular and the two circumflex arteries anastomosing with the superior profunda from the brachial, which will be afterward referred to as performing the same office after ligation of the brachial. The cases in which the operation has been performed are few in number, and no published account of dissection of the collateral circulation appears to exist.

BRANCHES OF THE AXILLARY ARTERY.

The branches of the axillary nerve are—

<i>From first part</i>	{ Superior Thoracic. Acromial Thoracic.	<i>From second part</i>	{ Long Thoracic. Alar Thoracic.
<i>From third part</i>	{ Subscapular. Anterior Circumflex. Posterior Circumflex.		

The **superior thoracic** is a small artery which arises from the axillary separately or by a common trunk with the acromial thoracic. Running forward and inward along the upper border of the Pectoralis minor, it passes between it and the Pectoralis major to the side of the chest. It supplies these muscles and the parietes of the thorax, anastomosing with the internal mammary and intercostal arteries.

The **acromial thoracic** is a short trunk which arises from the fore part of the axillary artery. Projecting forward to the upper border of the Pectoralis minor, it divides into three sets of branches—*thoracic*, *acromial*, and *descending*. The *thoracic branches*, two or three in number, are distributed to the Serratus magnus and Pectoral muscles, anastomosing with the intercostal branches of the internal mammary. The *acromial branches* are directed outward toward the acromion, supplying the Deltoid muscle, and anastomosing, on the surface of the acromion, with the suprascapular and posterior circumflex arteries. The *descending branch* passes in the space between the Pectoralis major and Deltoid in the same groove as the cephalic vein, and supplies both muscles. The artery also gives off a very small branch, the *clavicular*, which passes upward to the Subclavius muscle.

The **long thoracic** passes downward and inward along the lower border of the Pectoralis minor to the side of the chest, supplying the Serratus magnus, the Pectoral muscles, and mammary gland, and sending branches across the axilla to the axillary glands and Subscapularis; it anastomoses with the internal mammary and intercostal arteries.

The **alar thoracic** is a small branch which supplies the glands and areolar tissue of the axilla. Its place is frequently supplied by branches from some of the other thoracic arteries.

The **subscapular**, the largest branch of the axillary artery, arises opposite the lower border of the Subscapularis muscle, and passes downward and backward along its lower margin to the inferior angle of the scapula, where it anastomoses with the long thoracic and intercostal arteries and with the posterior scapular, a branch of the transversalis colli, from the thyroid axis of the subclavian. About an inch and a half from its origin it gives off a large branch, the *dorsalis scapulae*, and terminates by supplying branches to the muscles in the neighborhood.

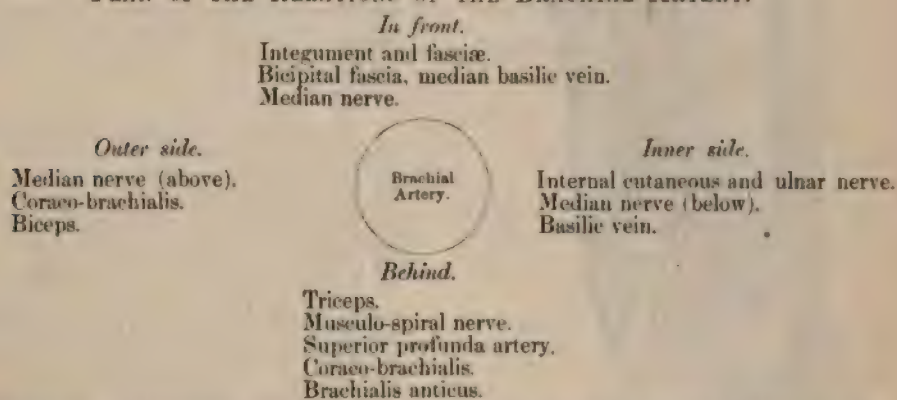

The **dorsalis scapulae** is given off from the subscapular about an inch from its origin, and is generally larger than the continuation of the vessel. It curves round the axillary border of the scapula, leaving the axilla through the space between the Teres minor above, the Teres major below, and the long head of the Triceps externally (Fig. 361), and enters the infraspinous fossa, where it anastomoses with the posterior scapular and suprascapular arteries. In its course it gives off two sets of branches: one enters the subscapular fossa beneath the Subscapularis, which it supplies, anastomosing with the posterior scapular and suprascapular arteries; the other is continued along the axillary border of the scapula, between the Teres major and minor, and, at the dorsal surface of the inferior angle of the bone, anastomoses with the posterior scapular. In addition to these, small branches are distributed to the back part of the Deltoid muscle and the long head of the Triceps, anastomosing with an ascending branch of the superior profunda of the brachial.

The **circumflex arteries** wind round the neck of the humerus. The *posterior circumflex* (Fig. 361), the larger of the two, arises from the back part of the axillary opposite the lower border of the Subscapularis muscle, and, passing backward with the circumflex veins and nerve through the quadrangular space bounded by the Teres major and minor, the scapular head of the Triceps and the humerus, winds round the neck of that bone and is distributed to the Deltoid muscle and shoulder-joint, anastomosing with the anterior circumflex and acromial thoracic arteries, and with the superior profunda branch of the brachial artery. The *anterior circumflex* (Figs. 361, 362), considerably smaller than the preceding, arises just below that vessel from the outer side of the axillary artery. It passes horizontally outward beneath the Coraco-brachialis and short head of the Biceps, lying upon the fore part of the neck of the humerus, and, on reaching the bicipital groove, gives off an ascending branch which passes upward along the groove to supply the head of the bone and the shoulder-joint. The trunk of the vessel is then continued outward beneath the Deltoid, which it supplies, and anastomoses with the posterior circumflex artery.

THE BRACHIAL ARTERY (Fig. 363).

The **Brachial Artery** commences at the lower margin of the tendon of the Teres major, and, passing down the inner and anterior aspect of the arm, terminates about half an inch below the bend of the elbow, where it divides into the *radial* and *ulnar arteries*.

PLAN OF THE RELATIONS OF THE BRACHIAL ARTERY.

Relations.—This artery is superficial throughout its entire extent, being covered, *in front*, by the integument, the superficial and deep fascia; the bicipital fascia separates it opposite the elbow from the median basilic vein; the median nerve crosses it at its middle. *Behind*, it is separated from the inner side of the humerus, above, by the long and inner heads of the Triceps, the musculo-spiral nerve and superior profunda artery intervening, and from the front of the bone, below, by the insertion of the Coraco-brachialis muscle and by the Brachialis anticus. By its *outer side* it is in relation with the commencement of the median nerve and the Coraco-brachialis and Biceps muscles, which slightly overlap the artery. By its *inner side* its upper half is in relation with the internal cutaneous and ulnar nerves, its lower half with the median nerve. The basilic vein lies on the inner side of the artery, but is separated from it in the lower part of the arm by the deep fascia. It is accompanied by two venæ comites, which lie in close contact with the artery, being connected together at intervals by short transverse communicating branches.

SURGICAL ANATOMY OF THE BEND OF THE ELBOW.

At the bend of the elbow the brachial artery sinks deeply into a triangular interval, the base of which is directed upward toward the humerus,

and the sides of which are bounded, externally, by the Supinator longus; internally, by the Pronator radii teres; its floor is formed by the Brachialis

FIG. 363.—The surgical anatomy of the brachial artery.

anticus and Supinator brevis. This space contains the brachial artery, with its accompanying veins, the radial and ulnar arteries, the median and musculo-spiral nerves, and the tendon of the Biceps. The brachial artery occupies the middle line of this space, and divides opposite the neck of the radius into the radial and ulnar arteries; it is covered, *in front*, by the integument, the superficial fascia, and the median basilic vein, the vein being separated from direct contact with the artery by the bicipital fascia. *Behind*, it lies on the Brachialis anticus, which separates it from the elbow-joint. The median nerve lies on the inner side of the artery, close to it above, but separated from it below by the coronoid head of the Pronator radii teres. The tendon of the Biceps lies to the outer side of the space, and the musculo-spiral nerve still more externally, lying upon the Supinator brevis and partly concealed by the Supinator longus.

Peculiarities of the Brachial Artery as regards its Course.—The brachial artery, accompanied by the median nerve, may leave the inner border of the Biceps, and descend toward the inner condyle of the humerus, where it usually curves round a prominence of bone, to which it is connected by a fibrous band; it then inclines outward, beneath or through the substance of the Pronator radii teres muscle, to the bend of the elbow. The variation bears considerable analogy with the normal condition of the artery in some of the carnivora: it has been referred to above in the description of the humerus (page 252).

As regards its Division.—Occasionally, the artery is divided for a short distance at its upper part into two trunks, which are united above and below. A similar peculiarity occurs in the main vessel of the lower limb.

The point of bifurcation may be above or below the usual point, the former condition being by far the more frequent. Out of 481 examinations recorded by Mr. Quain, some made on the right and some on the left side of the body, in 386 the artery bifurcated in its normal position. In one case only was the place of division lower than usual, being two or three inches below the elbow-joint. "In 94 cases out of 481, or about 1 in 5 $\frac{1}{4}$, there were two arteries instead of one in some part or in the whole of the arm."

There appears, however, to be no correspondence between the arteries of the two arms with respect to their irregular division; for in 61 bodies it occurred on one side only in 43; on both sides, in different positions, in 13; on both sides, in the same position, in 5.

The point of bifurcation takes place at different parts of the arm, being most frequent in the upper part, less so in the lower part, and least so in the middle, the most usual point for the application of a ligature; under any of these circumstances two large arteries would be found in the arm instead of one. The most frequent (in three out of four) of these peculiarities is the high division of the radial. That artery often arises from the inner side of the brachial, and runs parallel with the main trunk to the elbow, where it crosses it, lying beneath the fascia; or it may perforate the fascia and pass over the artery immediately beneath the integument.

The ulnar sometimes arises from the brachial high up, and then occasionally leaves that vessel at the lower part of the arm, and descends toward the inner condyle. In the forearm it gen-

erally lies beneath the deep fascia, superficial to the flexor muscles; occasionally between the integument and deep fascia, and very rarely beneath the flexor muscles.

The interosseous artery sometimes arises from the upper part of the brachial or axillary; as it passes down the arm it lies behind the main trunk, and at the bend of the elbow regains its usual position.

In some cases of high division of the radial the remaining trunk (ulnar interosseous) occasionally passes, together with the median nerve, along the inner margin of the arm to the inner condyle, and then passing from within outward, beneath or through the Pronator radii teres, regains its usual position at the bend of the elbow.

Occasionally the two arteries representing the brachial are connected at the bend of the elbow by a short transverse branch, and are even sometimes reunited.

Sometimes, long slender vessels, *vasa aberrantia*, connect the brachial or axillary arteries with one of the arteries of the forearm or a branch from them. These vessels usually join the radial.

Varieties in Muscular Relations.¹—The brachial artery is occasionally concealed in some part of its course by muscular or tendinous slips derived from the Coraco-brachialis, Biceps, Brachialis anticus and Pronator radii teres muscles.

Surface Marking.—The direction of the brachial artery is marked, when the arm is extended and supinated, by a line drawn from the junction of the anterior and middle third of the space between the anterior and posterior folds of the axilla; that is to say from the inner side of the prominence of the Coraco-brachialis muscle to the point midway between the condyles of the humerus which corresponds to the depression along the inner border of the Coraco-brachialis and Biceps. In the upper part of its course the artery lies internal to the humerus, but below it is in front of that bone.

Surgical Anatomy.—Compression of the brachial artery is required in cases of amputation and some other operations in the arm and forearm; and it will be observed that it may be effected in almost any part of the course of the artery. If pressure is made in the upper part of the limb, it should be directed from within outward; and if in the lower part, from before backward, as the artery lies on the inner side of the humerus above and in front below. The most favorable situation is about the middle of the arm, where it lies on the tendon of the Coraco-brachialis on the inner flat side of the humerus.

The application of a ligature to the brachial artery may be required in case of wound of the vessel and in some cases of wound of the palmar arch. It is also sometimes necessary in cases of aneurism of the brachial, the radial, ulnar, or interosseous arteries. The artery may be secured in any part of its course. The chief guides in determining its position are the surface markings produced by the inner margin of the Coraco-brachialis and Biceps, the known course of the vessel, and its pulsation, which should be carefully felt for before any operation is performed, as the vessel occasionally deviates from its usual position in the arm. In whatever situation the operation is performed, great care is necessary, on account of the extreme thinness of the parts covering the artery and the intimate connection which the vessel has throughout its whole course with important nerves and veins. Sometimes a thin layer of muscular fibre is met with concealing the artery; if such is the case, it must be cut across in order to expose the vessel.

In the upper third of the arm the artery may be exposed in the following manner: The patient being placed horizontally upon a table, the affected limb should be raised from the side and the hand supinated. An incision about two inches in length should be made on the inner side of the Coraco-brachialis muscle, and the subjacent fascia cautiously divided, so as to avoid wounding the internal cutaneous nerve or basilic vein, which sometimes runs on the surface of the artery as high as the axilla. The fascia having been divided, it should be remembered that the ulnar and internal cutaneous nerves lie on the inner side of the artery, the median on the outer side, the latter nerve being occasionally superficial to the artery in this situation, and that the *venae comites* are also in relation with the vessel, one on either side. These being carefully separated, the aneurism needle should be passed round the artery from the inner to the outer side.

If two arteries are present in the arm in consequence of a high division, they are usually placed side by side; and if they are exposed in an operation, the surgeon should endeavor to ascertain, by alternately pressing on each vessel, which of the two communicates with the wound or aneurism, when a ligature may be applied accordingly; or if pulsation or hemorrhage ceases only when both vessels are compressed, both vessels may be tied, as it may be concluded that the two communicate above the seat of disease or are reunited.

It should also be remembered that two arteries may be present in the arm in a case of high division, and that one of these may be found along the inner intermuscular septum, in a line toward the inner condyle of the humerus, or in the usual position of the brachial, but deeply placed beneath the common trunk: a knowledge of these facts will suggest the precautions necessary in every case, and indicate the measures to be adopted when anomalies are met with.

In the middle of the arm the brachial artery may be exposed by making an incision along the inner margin of the Biceps muscle. The forearm being bent so as to relax the muscle, it should be drawn slightly aside, and, the fascia being carefully divided, the median nerve will be

¹ See Struther's *Anatomical and Physiological Observations*.

exposed lying upon the artery (sometimes beneath); this being drawn inward and the muscle outward, the artery should be separated from its accompanying veins and secured. In this situation the inferior profunda may be mistaken for the main trunk, especially if enlarged, from the collateral circulation having become established; this may be avoided by directing the incision externally toward the Biceps, rather than inward or backward toward the Triceps.

The lower part of the brachial artery is of interest in a surgical point of view, on account of the relation which it bears to the veins most commonly opened in venesection. Of these vessels, the median basilic is the largest and most prominent, and, consequently, the one usually selected for the operation. It should be remembered that this vein runs parallel with the brachial artery, from which it is separated by the bicipital fascia, and that care should be taken in opening the vein not to carry the incision too deeply, so as to endanger the artery.

Collateral Circulation.—After the application of a ligature to the brachial artery in the upper third of the arm, the circulation is carried on by branches from the circumflex and subscapular arteries, anastomosing with ascending branches from the superior profunda. If the brachial is tied *below* the origin of the profunda arteries, the circulation is maintained by the branches of the profunda, anastomosing with the recurrent radial, ulnar, and interosseous arteries. In two cases described by Mr. South,¹ in which the brachial artery had been tied some time previously, in one "a long portion of the artery had been obliterated, and sets of vessels are descending on either side from above the obliteration, to be received into others which ascend in a similar manner from below it. In the other the obliteration is less extensive, and a single curved artery about as big as a crow-quill passes from the upper to the lower open part of the artery."

The branches of the brachial artery are—the

Superior Profunda.
Nutrient.

Inferior Profunda.
Anastomotica Magna.

Muscular.

The **superior profunda** arises from the inner and back part of the brachial, just below the lower border of the Teres major, and passes backward to the interval between the outer and inner heads of the Triceps muscle, accompanied by the musculo-spiral nerve; it winds round the back part of the shaft of the humerus in the spiral groove, between the Triceps and the bone, to the outer side of the humerus just above the external condyle, where it divides into two terminal branches. One of these pierces the external intermuscular septum, and descends to the space between the Brachialis anticus and Supinator longus, where it anastomoses with the recurrent branch of the radial artery; while the other, the *posterior articular*, descends along the back of the external intermuscular septum to the back part of the elbow-joint, where it anastomoses with the posterior interosseous recurrent, and across the back of the humerus with the posterior ulnar recurrent, the anastomotica magna, and inferior profunda (Fig. 366). The superior profunda supplies the Triceps muscle and gives off a nutrient artery to the upper end of the humerus. Near its commencement it sends off a branch which passes upward between the external and long heads of the Triceps muscle to anastomose with the posterior circumflex artery, and, while in the groove, a small branch which accompanies a branch of the musculo-spiral nerve through the substance of the Triceps muscle and ends in the Anconeus below the outer condyle of the humerus.

The **nutrient artery** of the shaft of the humerus arises from the brachial, about the middle of the arm. Passing downward it enters the nutrient canal of that bone near the insertion of the Coraco-brachialis muscle.

The **inferior profunda**, of small size, arises from the brachial, a little below the middle of the arm; piercing the internal intermuscular septum, it descends on the surface of the inner head of the Triceps muscle to the space between the inner condyle and olecranon, accompanied by the ulnar nerve, and terminates by anastomosing with the posterior ulnar recurrent and anastomotica magna. It also supplies a branch to the front of the internal condyle, which anastomoses with the anterior ulnar recurrent.

The **anastomotica magna** arises from the brachial about two inches above the

¹ Chelius's *Surgery*, vol. ii. p. 254. See also White's engraving, referred to by Mr. South, of the anastomosing branches after ligature of the brachial, in White's *Cases in Surgery*. Porta also gives a case (with drawings) of the circulation after ligature of both brachial and radial (*Alterazioni Patologiche delle Arterie*).

elbow-joint. It passes transversely inward upon the Brachialis anticus, and, piercing the internal intermuscular septum, winds round the back part of the humerus between the Triceps and the bone, forming an arch above the olecranon fossa by its junction with the posterior articular branch of the superior profunda. As this vessel lies on the Brachialis anticus, branches ascend to join the inferior profunda, and others descend in front of the inner condyle to anastomose with the anterior ulnar recurrent. Behind the internal condyle an offset is given off which anastomoses with the inferior profunda and posterior ulnar recurrent arteries and supplies the Triceps.

The **muscular** are three or four large branches, which are distributed to the muscles in the course of the artery. They supply the Coraco-brachialis, Biceps, and Brachialis anticus muscles.

The Anastomosis around the Elbow-joint (Fig. 366).—The vessels engaged in this anastomosis may be conveniently divided into those situated *in front* and *behind* the internal and external condyles. The branches anastomosing *in front* of the internal condyle are the anastomotica magna, the anterior ulnar recurrent, and the anterior terminal branch of the inferior profunda. Those *behind* the internal condyle are the anastomotica magna, the posterior ulnar recurrent, and the posterior terminal branch of the inferior profunda. The branches anastomosing *in front* of the external condyle are the radial recurrent and one of the terminal branches of the superior profunda. Those *behind* the external condyle (perhaps more properly described as being situated between the external condyle and the olecranon) are the anastomotica magna, the interosseous recurrent, and one of the terminal branches of the superior profunda. There is also a large arch of anastomosis above the olecranon, formed by the interosseous recurrent, joining with the anastomotica magna and posterior ulnar recurrent (Fig. 366).

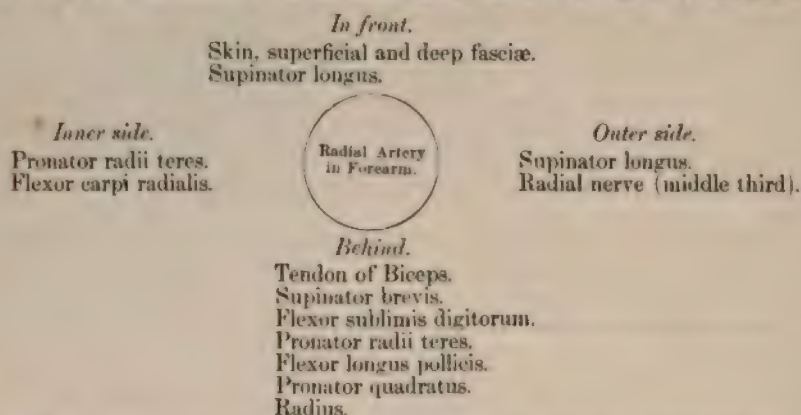

From this description it will be observed that the anastomotica magna is the vessel most engaged, the only part of the anastomosis in which it is not employed being that *in front* of the external condyle.

Radial Artery.

The **Radial Artery** appears, from its direction, to be the continuation of the brachial, but in size it is smaller than the ulnar. It commences at the bifurcation of the brachial, just below the bend of the elbow, and passes along the radial side of the forearm to the wrist; it then winds backward, round the outer side of the carpus, beneath the extensor tendons of the thumb, and, finally, passes forward, between the two heads of the First dorsal interosseous muscle, into the palm of the hand, where it crosses the metacarpal bones to the ulnar border of the hand, to form the deep palmar arch. At its termination it inosculates with the deep branch of the ulnar artery. The relations of this vessel may thus be conveniently divided into three parts—viz. in the forearm, at the back of the wrist, and in the hand.

Relations.—*In the forearm* this vessel extends from opposite the neck of the radius to the fore part of the styloid process, being placed to the inner side of the shaft of the bone above and in front of it below. It is superficial throughout its entire extent, being covered by the integument, the superficial and deep fasciæ, and slightly overlapped above by the Supinator longus. In its course downward it lies upon the tendon of the Biceps, the Supinator brevis, the radial origin of the Flexor sublimis digitorum, the Pronator radii teres, the Flexor longus pollicis, the Pronator quadratus, and the lower extremity of the radius. In the upper third of its course it lies between the Supinator longus and the Pronator radii teres; in its lower two-thirds, between the tendons of the Supinator longus and the Flexor carpi radialis. The radial nerve lies along the outer side of the artery in the middle third of its course, and some filaments of the musculo-cutaneous nerve, after piercing the deep fascia, run along the lower part of the artery as it winds round the wrist. The vessel is accompanied by venæ comites throughout its whole course.

PLAN OF THE RELATIONS OF THE RADIAL ARTERY IN THE FOREARM.

At the wrist, as it winds round the outer side of the carpus from the styloid process to the first interosseous space, it lies upon the external lateral ligament, and then upon the scaphoid bone and trapezium, being covered by the extensor tendons of the thumb, subcutaneous veins, some filaments of the radial nerve, and the integument. It is accompanied by two veins and a filament of the musculocutaneous nerve.

In the hand it passes from the upper end of the first interosseous space, between the heads of the Abductor indicis or First dorsal interosseous muscle, transversely across the palm, to the base of the metacarpal bone of the little finger, where it anastomoses with the communicating branch from the ulnar artery, forming the deep palmar arch. It lies upon the carpal extremities of the metacarpal bones and the Interossei muscles, being covered by the Adductor obliquus pollicis, the flexor tendons of the fingers, the Lumbricales, the Opponens, and Flexor brevis minimi digiti. Alongside of it is the deep branch of the ulnar nerve, but running in the opposite direction; that is to say, from within outward.

Peculiarities.—The origin of the radial artery, according to Quain, is, in nearly one case in eight, higher than usual; more frequently arising from the axillary or upper part of the brachial than from the lower part of this vessel. The variations in the position of this vessel in the arm and at the bend of the elbow have been already mentioned. In the forearm it deviates less frequently from its position than the ulnar. It has been found lying over the fascia instead of beneath it. It has also been observed on the surface of the Supinator longus, instead of along its inner border; and in turning round the wrist it has been seen lying over, instead of beneath, the extensor tendons.

Surface Marking.—The position of the radial artery in the forearm is represented by a line drawn from the outer border of the tendon of the Biceps in the centre of the hollow in front of the elbow-joint with a straight course to the inner side of the fore part of the styloid process of the radius.

Surgical Anatomy.—The radial artery is much exposed to injury in its lower third, and is frequently wounded by the hand being driven through a pane of glass, by the slipping of a knife or chisel held in the other hand, and such-like accidents. The injury is often followed by a traumatic aneurism, for which the old operation of laying open the sac and securing the vessel above and below is required.

The operation of tying the radial artery is required in cases of wounds either of its trunk or of some of its branches, or for aneurism; and it will be observed that the vessel may be exposed in any part of its course through the forearm without the division of any muscular fibres. The operation in the middle or inferior third of the forearm is easily performed, but in the upper third, near the elbow, it is attended with some difficulty, from the greater depth of the vessel and from its being overlapped by the Supinator longus muscle.

To tie the artery in the upper third an incision three inches in length should be made through the integument, in a line drawn from the centre of the bend of the elbow to the front of the styloid process of the radius, avoiding the branches of the median vein; the fascia of the arm being divided and the Supinator longus drawn a little outward, the artery will be exposed. The venæ comites should be carefully separated from the vessel, and the ligature passed from the radial to the ulnar side.

In the middle third of the forearm the artery may be exposed by making an incision of similar length on the inner margin of the Supinator longus. In this situation the radial nerve

lies in close relation with the outer side of the artery, and should, as well as the veins, be carefully avoided.

In the lower third the artery is easily secured by dividing the integument and fascia in the interval between the tendons of the Supinator longus and Flexor carpi radialis muscles.

The branches of the radial artery may be divided into three groups, corresponding with the three regions in which the vessel is situated.

<i>In the Forearm.</i>	{	Radial Recurrent.
		Muscular.
		Anterior Carpal.
		Superficialis Volæ.
<i>Wrist.</i>	{	Posterior Carpal.
		Metacarpal.
		Dorsalis Pollicis.
		Dorsalis Indicis.
<i>Hand.</i>	{	Princeps Pollicis.
		Radialis Indicis.
		Perforating.
		Interosseous.
	{	Palmar Recurrent.

The **radial recurrent** is given off immediately below the elbow. It ascends between the branches of the musculo-spiral nerve lying on the Supinator brevis, and then between the Supinator longus and Brachialis anticus, supplying these muscles and the elbow-joint, and anastomosing with one of the terminal branches of the superior profunda.

The **muscular branches** are distributed to the muscles on the radial side of the forearm.

The **anterior carpal** is a small vessel which arises from the radial artery near the lower border of the Pronator quadratus, and, running inward in front of the radius, anastomoses with the anterior carpal branch of the ulnar artery. From the arch thus formed branches descend to supply the articulations of the wrist.

The **superficialis volæ** arises from the radial artery, just where this vessel is about to wind round the wrist. Running forward, it passes between the muscles of the thumb, which it supplies, and sometimes anastomoses with the palmar portion of the ulnar artery, completing the superficial palmar arch. This vessel varies considerably in size:

FIG. 364.—The surgical anatomy of the radial and ulnar arteries.

usually it is very small, and terminates in the muscles of the thumb; sometimes it is as large as the continuation of the radial.

The **posterior carpal** is a small vessel which arises from the radial artery

FIG. 365.—Ulnar and radial arteries. Deep view

The **dorsalis indicis**, also a small branch, runs along the radial side of the back of the index finger, sending a few branches to the Abductor indicis.

The **princeps pollicis** arises from the radial just as it turns inward to the deep part of the hand; it descends between the Abductor indicis and Adductor obliquus pollicis, then between the Adductor transversus pollicis and Adductor obliquus pollicis, along the ulnar side of the metacarpal bone of the thumb, to the base of the first phalanx, where it divides into two branches, which run along the sides of the palmar aspect of the thumb and form an arch on the under surface

beneath the extensor tendons of the thumb; crossing the carpus transversely to the inner border of the hand, it anastomoses with the posterior carpal branch of the ulnar, forming the posterior carpal arch, which is joined by the termination of the posterior interosseous artery. From this arch are given off descending branches, the **dorsal interosseous arteries** for the third and fourth interosseous spaces, which run forward on the Third and Fourth dorsal interossei muscles and divide into dorsal digital branches which supply the adjacent sides of the middle, ring, and little fingers respectively, communicating with the digital arteries of the superficial palmar arch. At their origin they anastomose with the perforating branches from the deep palmar arch.

The **metacarpal (first dorsal interosseous branch)** arises beneath the extensor tendons of the thumb, sometimes with the posterior carpal artery; running forward on the Second dorsal interosseous muscle, it communicates, behind, with the corresponding perforating branch of the deep palmar arch; and in front it divides into two **dorsal digital branches**, which supply the adjoining sides of the index and middle fingers, inosculating with the digital branch of the superficial palmar arch.

The **dorsales pollicis** are two small vessels which run along the sides of the dorsal aspect of the thumb. They arise separately, or occasionally by a common trunk, near the base of the first metacarpal bone.

of the last phalanx, from which branches are distributed to the integument and pulp of the thumb.

The **radialis indicis** arises close to the preceding, descends between the Abductor indicis and Adductor transversus pollicis, and runs along the radial side of the index finger to its extremity, where it anastomoses with the collateral digital artery from the superficial palmar arch. At the lower border of the Adductor transversus pollicis this vessel anastomoses with the princeps pollicis, and gives a communicating branch to the superficial palmar arch.

The **perforating arteries**, three in number, pass backward between the heads of the last three Dorsal interossei muscles, to inosculate with the dorsal interosseous arteries.

The **palmar interosseous**, three or four in number, are branches of the deep palmar arch; they run forward upon the Interossei muscles, and anastomose at the clefts of the fingers with the digital branches of the superficial arch.

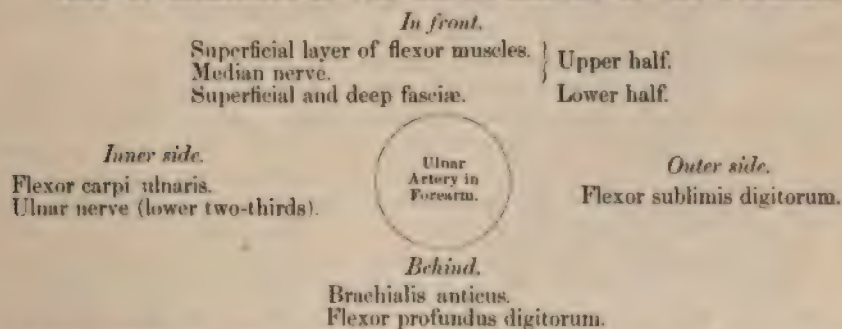

The **palmar recurrent branches** arise from the concavity of the deep palmar arch. They pass upward in front of the wrist, supplying the carpal articulations and anastomosing with the anterior carpal arch.

Ulnar Artery.

The **Ulnar Artery**, the larger of the two terminal branches of the brachial, commences a little below the bend of the elbow, and crosses obliquely the inner side of the forearm, to the commencement of its lower half; it then runs along its ulnar border to the wrist, crosses the annular ligament on the radial side of the pisiform bone, and immediately beyond this bone divides into two branches, superficial and deep palmar.

Relations in the Forearm.—In its *upper half* it is deeply seated, being covered by all the superficial flexor muscles, excepting the Flexor carpi ulnaris; it is crossed by the median nerve, which lies to its inner side for about an inch, and it lies upon the Brachialis anticus and Flexor profundus digitorum muscles. In the *lower half* of the forearm it lies upon the Flexor profundus, being covered by the integument, the superficial and deep fasciæ, and is placed between the Flexor carpi ulnaris and Flexor sublimis digitorum muscles. It is accompanied by two venæ comites; the ulnar nerve lies on its inner side for the lower two-thirds of its extent, and a small branch from the nerve descends on the lower part of the vessel to the palm of the hand.

PLAN OF RELATIONS OF THE ULNAR ARTERY IN THE FOREARM.

At the wrist (Fig. 364) the ulnar artery is covered by the integument and fascia, and lies upon the anterior annular ligament. On its inner side is the pisiform bone. The ulnar nerve lies at the inner side, and somewhat behind the artery.

Peculiarities.—The ulnar artery has been found to vary in its origin nearly in the proportion of one in thirteen cases, in one case arising lower than usual, about two or three inches below the elbow, and in all other cases much higher, the brachial being a more frequent source of origin than the axillary.

Variations in the position of this vessel are more frequent than in the radial. When its origin is normal the course of the vessel is rarely changed. When it arises high up it is almost invariably superficial to the flexor muscles in the forearm, lying commonly beneath the fascia, more rarely between the fascia and integument. In a few cases its position was subcutaneous in the upper part of the forearm, subaponeurotic in the lower part.

Surface Marking.—On account of the curved direction of the ulnar artery the line on the surface of the body which indicates its course is somewhat complicated. First, draw a line from the front of the internal condyle of the humerus to the radial side of the pisiform bone; the lower two-thirds of this line represents the course of the middle and lower third of the ulnar artery. Secondly, draw a line from the centre of the hollow in front of the elbow-joint to the junction of the upper and middle third of the first line; this represents the course of the upper third of the artery.

Surgical Anatomy.—The application of a ligature to this vessel is required in cases of wound of the artery or of its branches, or in consequence of aneurism. In the upper half of the forearm the artery is deeply seated beneath the superficial flexor muscles, and the application of a ligature in this situation is attended with some difficulty. An incision is to be made in the course of a line drawn from the front of the internal condyle of the humerus to the outer side of the pisiform bone, so that the centre of the incision is three fingers' breadth below the internal condyle. The skin and superficial fascia having been divided and the deep fascia exposed, the white line which separates the Flexor carpi ulnaris from the other flexor muscles is to be sought for, and the fascia incised in this line. The Flexor carpi ulnaris is now to be carefully separated from the other muscles, when the ulnar nerve will be exposed, and must be drawn aside. Some little distance below the nerve the artery will be found accompanied by its venæ comites, and may be ligatured by passing the needle from within outward. In the middle and lower third of the forearm this vessel may be easily secured by making an incision on the radial side of the tendon of the Flexor carpi ulnaris; the deep fascia being divided, and the Flexor carpi ulnaris and its companion muscle, the Flexor sublimis, being separated from each other, the vessel will be exposed, accompanied by its venæ comites, the ulnar nerve lying on its inner side. The veins being separated from the artery, the ligature should be passed from the ulnar to the radial side, taking care to avoid the ulnar nerve.

The branches of the ulnar artery may be arranged in the following groups:

	{ Anterior Ulnar Recurrent.
	{ Posterior Ulnar Recurrent.
<i>Forearm.</i>	{ Interosseous { Anterior Interosseous.
	{ { Posterior Interosseous.
	{ Muscular.
<i>Wrist.</i>	{ Anterior Carpal.
	{ Posterior Carpal.
<i>Hand.</i>	{ Superficial Palmar Arch.
	{ Deep Palmar or Communicating.

The **anterior ulnar recurrent** (Fig. 365) arises immediately below the elbow-joint, passes upward and inward between the Brachialis anticus and Pronator radii teres, supplies those muscles, and, in front of the inner condyle, anastomoses with the anastomotica magna and inferior profunda.

The **posterior ulnar recurrent** is much larger, and arises somewhat lower than the preceding. It passes backward and inward, beneath the Flexor sublimis, and ascends behind the inner condyle of the humerus. In the interval between this process and the olecranon it lies beneath the Flexor carpi ulnaris, ascending between the heads of that muscle, beneath the ulnar nerve; it supplies the neighboring muscles and joint, and anastomoses with the inferior profunda, anastomotica magna, and interosseous recurrent arteries (Fig. 366).

The **interosseous artery** (Fig. 365) is a short trunk about an inch in length, and of considerable size, which arises immediately below the tuberosity of the radius, and, passing backward to the upper border of the interosseous membrane, divides into two branches, the *anterior* and *posterior interosseous*.

The **anterior interosseous** passes down the forearm on the anterior surface of the interosseous membrane, to which it is connected by a thin aponeurotic arch. It is accompanied by the interosseous branch of the median nerve, and overlapped by the contiguous margins of the Flexor profundus digitorum and Flexor longus pollicis muscles, giving off in this situation muscular branches and the nutrient arteries of the radius and ulna. At the upper border of the Pronator quadratus a branch descends beneath the muscle to anastomose in front of the carpus with

branches from the anterior carpal and deep palmar arch. The continuation of the artery passes behind the Pronator quadratus, and, piercing the interosseous membrane, gets to the back of the forearm, and anastomoses with the posterior interosseous artery (Fig. 366). It then descends to the back of the wrist to join the posterior carpal arch. The anterior interosseous gives off a long, slender branch, the *median artery*, which accompanies the median nerve and gives offsets to its substance. This artery is sometimes much enlarged. It also gives off nutrient branches to the radius and ulna about the middle of the forearm.

The **posterior interosseous artery** passes backward through the interval between the oblique ligament and the upper border of the interosseous membrane. It appears between the contiguous borders of the Supinator brevis and the Extensor ossis metacarpi pollicis, and runs down the back part of the forearm, between the superficial and deep layer of muscles, to both of which it distributes branches. At the lower part of the forearm it anastomoses with the termination of the anterior interosseous artery. Then, continuing its course over the head of the ulna, it joins the posterior carpal branch of the ulnar artery. This artery gives off, near its origin, the *interosseous recurrent branch*.

The **interosseous recurrent artery** is a large vessel which ascends to the interval between the external condyle and olecranon, on or through the fibres of the Supinator brevis, but beneath the Anconeus, anastomosing with a branch from the superior profunda, and with the posterior ulnar recurrent and anastomotica magna.

The **muscular branches** are distributed to the muscles along the ulnar side of the forearm.

The **anterior carpal** is a small vessel which crosses the front of the carpus beneath the tendons of the Flexor profundus, and inosculates with a corresponding branch of the radial artery.

FIG. 366.—Arteries of the back of the forearm and hand.

The **posterior carpal** arises immediately above the pisiform bone, and winds backward beneath the tendon of the Flexor carpi ulnaris: it passes across the dorsal surface of the carpus beneath the extensor tendons, anastomosing with a corresponding branch of the radial artery, and forming the *posterior carpal arch*. Immediately after its origin it gives off a small branch which runs along the ulnar side of the metacarpal bone of the little finger, forming one of the *metacarpal arteries*, and supplies the ulnar side of the dorsal surface of the little finger.

The **deep palmar or communicating branch** (Fig. 365) passes deeply inward between the Abductor minimi digiti and Flexor brevis minimi digiti near their origins; it anastomoses with the termination of the radial artery, completing the deep palmar arch.

The Superficial Palmar Arch.—The superficial palmar arch passes outward across the palm of the hand, describing a curve, with its convexity forward to the space between the ball of the thumb and the index finger, where the arch is completed by its anastomosing with a branch from the radialis indicis, though sometimes the arch is completed by its anastomosing with the superficialis volæ branch of the radial artery.

Relations.—The superficial palmar arch is covered by the skin, the Palmaris brevis, and the palmar fascia. It lies upon the annular ligament, origin of the muscles of the little finger, the tendons of the superficial flexor of the fingers, and, the divisions of the median and ulnar nerves.

Divisions of median and ulnar nerves.

BRANCHES OF THE SUPERFICIAL PALMAR ARCH.

Digital.

The **digital branches** (Fig. 364), four in number, are given off from the convexity of the superficial palmar arch. They supply the ulnar side of the little finger and the adjoining sides of the little, ring, middle, and index fingers, the radial side of the index finger and thumb being supplied from the radial artery. The digital arteries at first lie superficial to the flexor tendons, but as they pass forward with the digital nerves to the clefts between the fingers they lie between them, and are there joined by the interosseous branches from the deep palmar arch. The digital arteries on the sides of the fingers lie beneath the digital nerves; and about the middle of the last phalanx the two branches for each finger form an arch, from the convexity of which branches pass to supply the pulp of the finger.

Surface Marking.—The superficial palmar arch is represented by a curved line, starting from the outer side of the pisiform bone and carried downward as far as the middle third of the palm, and then curved outward on a level with the upper end of the cleft between the thumb and index finger.

The deep palmar arch is situated about half an inch nearer to the carpus.

Surgical Anatomy.—Wounds of the palmar arches are of special interest, and are always difficult to deal with. When the wound in the superficial tissues is extensive, it may be possible to secure the bleeding ends of the vessel; but when there is a small punctured wound, as from a penknife or piece of glass, pressure systematically applied is probably the best course of treatment, as there is difficulty in reaching the wounded vessel without damaging important structures. At the same time it must be admitted that pressure applied to the palm of the hand to arrest hæmorrhage from a wound of one of the palmar arches, especially the deep arch, is apt to be followed by sloughing, owing to the rigidity of the parts and the facility with which a considerable amount of pressure can be applied. In wounds of the deep palmar arch a ligature may be applied to the bleeding points from the dorsum of the hand by resection of the upper part of the third metacarpal bone. It is useless in these cases to ligature one of the arteries of the forearm alone, and indeed simultaneous ligature of both radial and ulnar arteries above the wrist is often unsuccessful, on account of the anastomosis carried on by the carpal arches. Therefore, upon the failure of pressure to arrest hæmorrhage it is expedient to apply a ligature to the brachial artery.

THE DESCENDING AORTA.

ARTERIES OF THE TRUNK.

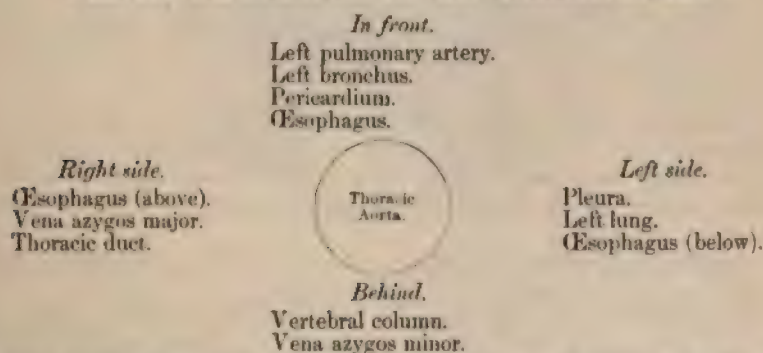

The **Descending Aorta** is divided into two portions, the *thoracic* and *abdominal*, in correspondence with the two great cavities of the trunk in which it is situated.

THE THORACIC AORTA.

The **Thoracic Aorta** commences at the lower border of the fourth dorsal vertebra, on the left side, and terminates at the aortic opening in the Diaphragm, in front of the last dorsal vertebra. At its commencement it is situated on the left side of the spine; it approaches the median line as it descends, and at its termination lies directly in front of the column. The direction of this vessel being influenced by the spine, upon which it rests, it describes a curve which is concave forward in the dorsal region. As the branches given off from it are small, the diminution in the size of the vessel is inconsiderable. It is contained in the back part of the posterior mediastinum.

Relations.—It is in relation, *in front*, from above downward, with the left pulmonary artery, the left bronchus, the pericardium, and the œsophagus; *behind*, with the vertebral column and the vena azygos minor; on the *right side*, with the vena azygos major and thoracic duct; on the *left side*, with the left pleura and lung. The œsophagus, with its accompanying nerves, lies on the right side of the aorta *above*, but at the lower part of the thorax it gets in front of the aorta, and close to the Diaphragm is situated to its left side.

PLAN OF THE RELATIONS OF THE THORACIC AORTA.

The aorta is occasionally found to be obliterated at a particular spot—viz. at the junction of the arch with the thoracic aorta, just below the ductus arteriosus. Whether this is the result of disease or of congenital malformation is immaterial to our present purpose; it affords an interesting opportunity of observing the resources of the collateral circulation. The course of the anastomosing vessels, by which the blood is brought from the upper to the lower part of the artery, will be found well described in an account of two cases in the *Pathological Transactions*, vols. viii. and x. In the former (p. 162) Mr. Sydney Jones thus sums up the detailed description of the

anastomosing vessels: "The principal communications by which the circulation was carried on, were—Firstly, the internal mammary, anastomosing with the intercostal arteries, with the phrenic of the abdominal aorta by means of the musculo-phrenic and comes nervi phrenici, and largely with the deep epigastric. Secondly, the superior intercostal, anastomosing anteriorly by means of a large branch with the first aortic intercostal, and posteriorly with the posterior branch of the same artery. Thirdly, the inferior thyroid, by means of a branch about the size of an ordinary radial, formed a communication with the first aortic intercostal. Fourthly, the transversalis colli, by means of very large communications with the posterior branches of the intercostals. Fifthly, the branches (of the subclavian and axillary) going to the side of the chest were large, and anastomosed freely with the lateral branches of the intercostals." In the second case also (vol. x. p. 97) Mr. Wood describes the anastomoses in a somewhat similar manner, adding the remark that "the blood which was brought into the aorta through the anastomoses of the intercostal arteries appeared to be expended principally in supplying the abdomen and pelvis, while the supply to the lower extremities had passed through the internal mammary and epigastrics."

Surgical Anatomy.—The student should now consider the effects likely to be produced by aneurism of the thoracic aorta, a disease of common occurrence. When we consider the great depth of the vessel from the surface and the number of important structures which surround it on every side, it may easily be conceived what a variety of obscure symptoms may arise from disease of this part of the arterial system, and how they may be liable to be mistaken for those of other affections. Aneurism of the thoracic aorta most usually extends backward along the left side of the spine, producing absorption of the bodies of the vertebrae, with curvature of the spine; whilst the irritation or pressure on the cord will give rise to pain, either in the chest, back, or loins, with radiating pain in the left upper intercostal spaces, from pressure on the intercostal nerves; at the same time the tumor may project backward on each side of the spine, beneath the integument, as a pulsating swelling, simulating abscess connected with diseased bone, or it may displace the œsophagus and compress the lung on one or the other side. If the tumor extend forward, it may press upon and displace the heart, giving rise to palpitation and other symptoms of disease of that organ; or it may displace, or even compress, the œsophagus, causing pain and difficulty of swallowing, as in stricture of that tube; and ultimately even open into it by ulceration, producing fatal hæmorrhage. If the disease extends to the right side, it may press upon the thoracic duct; or it may burst into the pleural cavity or into the trachea or lung; and lastly, it may open into the posterior mediastinum.

BRANCHES OF THE THORACIC AORTA.

Pericardiac.
Bronchial.

Œsophageal.
Posterior Mediastinal.

Intercostal.

The **pericardiac** are a few small vessels, irregular in their origin, distributed to the pericardium.

The **bronchial arteries** are the nutrient vessels of the lungs, and vary in number, size, and origin. That of the right side arises from the first aortic intercostal, or by a common trunk with the left bronchial from the front of the thoracic aorta. Those of the left side, usually two in number, arise from the thoracic aorta, one a little lower than the other. Each vessel is directed to the back part of the corresponding bronchus along which it runs, dividing and subdividing upon the bronchial tube, supplying them, the cellular tissue of the lungs, the bronchial glands, and the œsophagus.

The **œsophageal arteries**, usually four or five in number, arise from the front of the aorta, and pass obliquely downward to the œsophagus, forming a chain of anastomoses along that tube, anastomosing with the œsophageal branches of the inferior thyroid arteries above, and with ascending branches from the phrenic and gastric arteries below.

The **posterior mediastinal arteries** are numerous small vessels which supply the glands and loose areolar tissue in the mediastinum.

The **Intercostal arteries** arise from the back part of the aorta. They are usually eleven in number on each side, the superior intercostal space being supplied by the superior intercostal, a branch of the subclavian, and the second intercostal space being supplied by a branch from the superior intercostal joining with the first aortic intercostal. The lowest of these branches, the *subcostal artery*, underlies the last rib. The right intercostals are longer than the left, on account of the position of the aorta on the left side of the spine; they pass outward, across the bodies of the vertebrae, to the intercostal spaces, being covered by the pleura, the

œsophagus, thoracic duct, sympathetic nerve, and the vena azygos major; the left passing beneath the superior intercostal vein, the vena azygos minor, and sympathetic. In the intercostal spaces each artery divides into two branches—an anterior, or proper intercostal branch; and a posterior, or dorsal branch.¹

The anterior branch passes outward, at first lying upon the External inter-

FIG. 367.—The abdominal aorta and its branches.

costal muscle, covered in front by the pleura and a thin fascia. It then passes between the two layers of Intercostal muscles, and, having ascended obliquely to the lower border of the rib above, divides, near the angle of that bone, into two branches: of these the larger runs in the groove on the lower border of the rib above; the smaller branch along the upper border of the rib below; passing

¹ Mr. W. J. Walsham describes a small twig as being given off from each intercostal close to its origin. He states that they can be traced running between the neck of the rib and the transverse process of the corresponding vertebra; they anastomose with similar twigs given off from the intercostal artery next below. In the first and second spaces similar anastomosing twigs are given off from the superior intercostal (*Journal of Anatomy and Physiology*, vol. xvi. part iii. p. 443).

forward, they supply the Intercostal muscle, and anastomose with the anterior intercostal branches of the internal mammary, and with the thoracic branches of the axillary artery. The first aortic intercostal anastomoses with the superior intercostal, and the last three pass between the abdominal muscles, inosculating with the epigastric in front and with the phrenic and lumbar arteries. Each intercostal artery is accompanied by a vein and nerve, the former being above, and the latter below, except in the upper intercostal spaces, where the nerve is at first above the artery. The arteries are protected from pressure during the action of the Intercostal muscles by fibrous arches thrown across, and attached by each extremity to the bone. The lower intercostal arteries are continued anteriorly from the intercostal spaces into the abdominal wall, except the last, the *subcostal*, which lies throughout its whole course in the abdominal wall, since it is placed below the last rib. They pass behind the costal cartilages between the Internal oblique and Transversalis muscle to the sheath of the Rectus, where they anastomose with the internal mammary and the deep epigastric arteries. Behind, the subcostal artery anastomoses with the first lumbar artery.

The *posterior* or *dorsal branch* of each intercostal artery passes backward to the inner side of the anterior costo-transverse ligament, and divides into a muscular branch which is distributed to the muscles and integument of the back, and a spinal branch which enters the spinal canal through the intervertebral foramina to be distributed to the spinal cord and its membranes, and to the bodies of the vertebræ in the same manner as the lateral spinal branches from the vertebral.

THE ABDOMINAL AORTA (Fig. 367).

The *Abdominal Aorta* commences at the aortic opening of the Diaphragm, in front of the body of the last dorsal vertebra, and, descending a little to the left side of the vertebral column, terminates on the body of the fourth lumbar vertebra, commonly a little to the left of the middle line,¹ where it divides into the two common iliac arteries. It diminishes rapidly in size, in consequence of the many large branches which it gives off. As it lies upon the bodies of the vertebræ the curve which it describes is convex forward, the greatest convexity corresponding to the third lumbar vertebra, which is a little above and to the left side of the umbilicus.

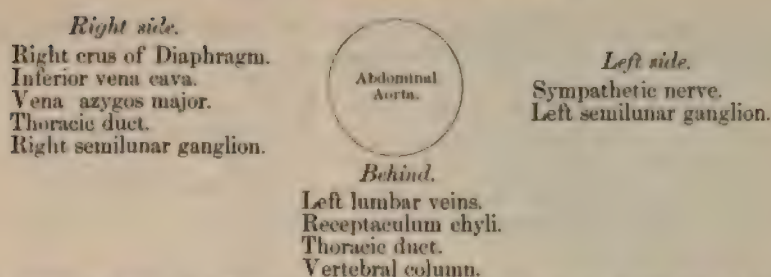

Relations.—It is covered, *in front*, by the lesser omentum and stomach, behind which are the branches of the celiac axis and the solar plexus; below these, by the splenic vein, the pancreas, the left renal vein, the transverse portion of the duodenum, the mesentery, and aortic plexus. *Behind*, it is separated from the lumbar vertebræ by the left lumbar veins, the receptaculum chyli, and thoracic duct. On the *right side* it is in relation with the inferior vena cava (the right crus of the Diaphragm being interposed above), the vena azygos major, thoracic duct, and right semilunar ganglion; on the *left side*, with the sympathetic nerve and left semilunar ganglion.

PLAN OF THE RELATIONS OF THE ABDOMINAL AORTA.

In front.

Lesser omentum and stomach.

Mesentery.
Aortic plexus.

¹ Sir Joseph Lister, having accurately examined 30 bodies in order to ascertain the exact point of termination of this vessel, found it "either absolutely, or almost absolutely, mesial in 15, while in 13 it deviated more or less to the left, and in 2 was slightly to the right" (*System of Surgery*, edited by T. Holmes, 2d ed. vol. v. p. 652).

Surface Marking.—In order to map out the abdominal aorta on the surface of the abdomen, a line must be drawn from the middle line of the body, on a level with the distal extremity of the seventh costal cartilage, downward and slightly to the left, so that it just skirts the umbilicus, to a zone drawn round the body opposite the highest point of the crest of the ilium. This point is generally half an inch below and to the left of the umbilicus, but as the position of this structure varies with the obesity of the individual, it is not a reliable landmark as to the situation of the bifurcation of the aorta.

Surgical Anatomy.—Aneurisms of the abdominal aorta near the celiac axis communicate in nearly equal proportion with the anterior and posterior parts of the artery.

When an aneurismal sac is connected with the back part of the abdominal aorta, it usually produces absorption of the bodies of the vertebrae, and forms a pulsating tumor that presents itself in the left hypochondriac or epigastric regions, and is accompanied by symptoms of disturbance in the alimentary canal. Pain is invariably present, and is usually of two kinds—a fixed and constant pain in the back, caused by the tumor pressing on or displacing the branches of the solar plexus and splanchnic nerves; and a sharp lancinating pain, radiating along those branches of the lumbar nerves which are pressed on by the tumor; hence the pain in the loins, the testes, the hypogastrium, and in the lower limb (usually of the left side). This form of aneurism usually bursts into the peritoneal cavity or behind the peritoneum in the left hypochondriac region; or it may form a large aneurismal sac, extending down as low as Poupart's ligament; hæmorrhage in these cases being generally very extensive, but slowly produced, and not rapidly fatal.

When an aneurismal sac is connected with the front of the aorta near the celiac axis, it forms a pulsating tumor in the left hypochondriac or epigastric regions, usually attended with symptoms of disturbance of the alimentary canal, as sickness, dyspepsia, or constipation, and accompanied by pain, which is constant, but nearly always fixed in the loins, epigastrium, or some part of the abdomen; the radiating pain being rare, as the lumbar nerves are seldom implicated. This form of aneurism may burst into the peritoneal cavity or behind the peritoneum, between the layers of the mesentery, or, more rarely, into the duodenum; it rarely extends backward so as to affect the spine.

The abdominal aorta has been tied several times, and although none of the patients permanently recovered, still, as one of them lived as long as ten days, the possibility of the re-establishment of the circulation may be considered to be proved. In the lower animals this artery has been often successfully tied. The vessel may be reached in several ways. In the original operation, performed by Sir A. Cooper, an incision was made in the linea alba, the peritoneum opened in front, the finger carried down amongst the intestines toward the spine, the peritoneum again opened behind by scratching through the mesentery, and the vessel thus reached. Or either of the operations described below for securing the common iliac artery may, by extending the dissection a sufficient distance upward, be made use of to expose the aorta. The chief difficulty in the dead subject consists in isolating the artery in consequence of its great depth; but in the living subject the embarrassment resulting from the proximity of the aneurismal tumor, and the great probability of disease in the vessel itself, add to the dangers and difficulties of this formidable operation so greatly that it is very doubtful whether it ought ever to be performed.

The collateral circulation would be carried on by the anastomosis between the internal mammary and the deep epigastric; by the free communication between the superior and inferior mesenterics if the ligature were placed above the latter vessel; or by the anastomosis between the inferior mesenteric and the internal pudic when (as is more common) the point of ligature is below the origin of the inferior mesenteric; and possibly by the anastomoses of the lumbar arteries with the branches of the internal iliac.

The circulation through the abdominal aorta may be commanded, in thin persons, by firm pressure with the fingers. A tourniquet has been invented for this purpose which is sometimes used in amputation at the hip-joint and some other operations.

BRANCHES OF THE ABDOMINAL AORTA.

Phrenic.		Superior Mesenteric.	Ovarian in female.
Celiac Axis.	{ Gastric.	Suprarenal.	Inferior Mesenteric.
	{ Hepatic.	Renal.	Lumbar.
	{ Splenic.	Spermatic in male.	Sacra Media.

The branches may be divided into two sets: 1. Those supplying the viscera.
2. Those distributed to the walls of the abdomen.

<i>Visceral Branches.</i>		Renal.

Inferior Mesenteric.		Phrenic.
Suprarenal.		Lumbar.
		Sacra Media.

Visceral Branches of the Abdominal Aorta.

The Celiac Axis (Fig. 368).

To expose this artery raise the liver, draw down the stomach, and then tear through the layers of the lesser omentum.

The **Celiac Axis** is a short thick trunk, about half an inch in length, which

FIG. 368.—The celiac axis and its branches, the liver having been raised and the lesser omentum removed.

arises from the aorta opposite the margin of the Diaphragm, and, passing nearly horizontally forward (in the erect posture), divides into three large branches, the *gastric*, *hepatic*, and *splenic*, occasionally giving off one of the phrenic arteries.

Relations.—It is covered by the lesser omentum. On the *right side* it is in relation with the right semilunar ganglion, and the lobus Spigelii; on the *left side*, with the left semilunar ganglion and cardiac end of the stomach. *Below*, it rests upon the upper border of the pancreas.

The **Gastric Artery** (*Coronaria ventriculi*), the smallest of the three branches of the coeliac axis, passes upward and to the left side, to the cardiac orifice of the stomach, distributing branches to the œsophagus which anastomose with the aortic œsophageal arteries; others supply the cardiac end of the stomach, inosculating with branches of the splenic artery; it then passes from left to right, along the lesser curvature of the stomach to the pylorus, lying in its course between the layers of the lesser omentum, and giving branches to both surfaces of the organ: at its termination it anastomoses with the pyloric branch of the hepatic.

The **Hepatic Artery** in the adult is intermediate in size between the gastric and splenic; in the fœtus it is the largest of the three branches of the coeliac axis. It is first directed forward and to the right, to the upper margin of the pyloric end of the stomach, forming the lower boundary of the foramen of Winslow. It then passes upward between the layers of the lesser omentum, and in front of the foramen of Winslow, to the transverse fissure of the liver, where it divides into two branches, right and left, which supply the corresponding lobes of that organ, accompanying the ramifications of the vena portæ and hepatic duct. The hepatic artery, in its course along the right border of the lesser omentum, is in relation with the ductus communis choledochus and portal veins, the duct lying to the right of the artery and the vena portæ behind.

Its branches are—the

Pyloric.

Gastro-duodenalis { Gastro-epiploica Dextra.
Pancreatico-duodenalis Superior.

Cystic.

The **pyloric branch** arises from the hepatic, above the pylorus, descends to the pyloric end of the stomach, and passes from right to left along its lesser curvature, supplying it with branches and inosculating with the gastric artery.

The **gastro-duodenalis** (Fig. 369) is a short but large branch which descends, near the pylorus, behind the first portion of the duodenum, and divides at the lower border of the stomach into two branches, the *gastro-epiploica dextra* and the *pancreatico-duodenalis superior*. Previous to its division it gives off two or three small inferior pyloric branches to the pyloric end of the stomach and pancreas.

The **gastro-epiploica dextra** runs from right to left along the greater curvature of the stomach, between the layers of the great omentum, anastomosing about the middle of the lower border of the stomach with the *gastro-epiploica sinistra* from the splenic artery. This vessel gives off numerous branches, some of which ascend to supply both surfaces of the stomach, whilst others descend to supply the great omentum.

The **pancreatico-duodenalis superior** descends between the contiguous margins of the duodenum and pancreas. It supplies both these organs, and anastomoses with the inferior pancreatico-duodenal branch of the superior mesenteric artery and with the pancreatic branches of the splenic.

The **cystic artery** (Fig. 368), usually a branch of the right hepatic, passes upward and forward along the neck of the gall-bladder, and divides into two branches, one of which ramifies on its free surface, the other between it and the substance of the liver.

The **Splenic Artery**, in the adult, is the largest of the three branches of the coeliac axis, and is remarkable for the extreme tortuosity of its course. It passes horizontally to the left side along the upper border of the pancreas, accompanied by the splenic vein, which lies below it, and on arriving near the spleen divides into branches, some of which enter the hilum of that organ to be distributed to its structure, whilst others are distributed to the great end of the stomach. Its branches are—the

Pancreaticæ Parvæ.

Pancreatica Magna.

Gastric (Vasa Brevia).

Gastro-epiploica Sinistra.

The **pancreatic** are numerous small branches derived from the splenic as it runs behind the upper border of the pancreas, supplying its middle and left parts. One of these, larger than the rest, is given off from the splenic near the left extremity of the pancreas; it runs from left to right near the posterior surface of the gland, following the course of the pancreatic duct, and is called the *pancreatica magna*. These vessels anastomose with the pancreatic branches of the pancreatico-

FIG. 369.—The celiac axis and its branches, the stomach having been raised and the transverse meso-colon removed.

duodenal arteries, derived from the hepatic on the one hand and superior mesenteric on the other.

The **gastric (vasa brevia)** consists of from five to seven small branches, which arise either from the termination of the splenic artery or from its terminal branches, and, passing from left to right, between the layers of the gastro-splenic omentum, are distributed to the great curvature of the stomach, anastomosing with branches of the gastric and gastro-epiploica sinistra arteries.

The **gastro-epiploica sinistra**, the largest branch of the splenic, runs from left to right along the great curvature of the stomach, between the layers of the great omentum, and anastomoses with the gastro-epiploica dextra. In its course it distributes several branches to the stomach, which ascend upon both surfaces; others descend to supply the omentum.

The Superior Mesenteric Artery (Fig. 370).

In order to expose this vessel raise the great omentum and transverse colon, draw down the small intestines, and cut through the peritoneum where the transverse meso-colon and mesen-

tery join: the artery will then be exposed just as it issues from beneath the lower border of the pancreas.

The **Superior Mesenteric Artery** supplies the whole length of the small intestine, except the first part of the duodenum; it also supplies the cæcum, ascending and transverse colon; it is a vessel of large size, arising from the fore part of the aorta about a quarter of an inch below the coeliac axis; being covered at its origin by the splenic vein and pancreas. It passes forward, between the pancreas and transverse portion of the duodenum, crosses in front of this portion of the intes-

FIG. 370.—The superior mesenteric artery and its branches.

tine, and descends between the layers of the mesentery to the right iliac fossa, where it terminates, considerably diminished in size. In its course it forms an arch, the convexity of which is directed forward and downward to the left side, the concavity backward and upward to the right. It is accompanied by the superior mesenteric vein, and is surrounded by a superior mesenteric plexus of nerves. Its branches are—the

Inferior Pancreatico-duodenal.

Vasa Intestini Tenuis.

Colica Media.

Ileo-colic.

Colica Dextra.

The **Inferior pancreatico-duodenal** is given off from the superior mesenteric behind the pancreas, and is distributed to the head of the pancreas with the

transverse and descending portions of the duodenum, anastomosing with the superior pancreatico-duodenal artery.

The *vasa intestini tenuis* arise from the convex side of the superior mesenteric artery. They are usually from twelve to fifteen in number, and are distributed to the jejunum and ileum. They run parallel with one another between the layers of the mesentery, each vessel dividing into two branches, which unite with a similar branch on each side, forming a series of arches the convexities of which are directed toward the intestine. From this first set of arches branches arise, which again unite with similar branches from either side, and thus a second series of arches is formed; and from these latter, a third, and a fourth, or even fifth, series of arches is constituted, diminishing in size the nearer they approach the intestine. From the terminal arches numerous small straight vessels arise which encircle the intestine, upon which they are distributed, ramifying thickly between its coats.

The *ileo-colic artery* is the lowest branch given off from the concavity of the superior mesenteric artery. It descends between the layers of the mesentery to the right iliac fossa, where it divides into two branches. Of these, the inferior one inosculates with the lowest branches of the *vasa intestini tenuis*, from the convexity of which branches proceed to supply the termination of the ileum, the cæcum and appendix cæci, and the ileo-cæcal valve. The superior division inosculates with the *colica dextra* and supplies the commencement of the colon.

The *colica dextra* arises from about the middle of the concavity of the superior mesenteric artery, and, passing behind the peritoneum to the middle of the ascending colon, divides into two branches—a descending branch, which inosculates with the *ileo-colic*; and the ascending branch, which anastomoses with the *colica media*. These branches form arches, from the convexity of which vessels are distributed to the ascending colon. The branches of this vessel are covered with peritoneum only on their anterior aspect.

The *colica media* arises from the upper part of the concavity of the superior mesenteric, and, passing forward between the layers of the transverse meso-colon, divides into two branches, the one on the right side inosculating with the *colica dextra*; that on the left side, with the *colica sinistra*, a branch of the inferior mesenteric. From the arches formed by their inosculation branches are distributed to the transverse colon. The branches of this vessel lie between two layers of peritoneum.

The Inferior Mesenteric Artery (Fig. 371).

In order to expose this vessel draw the small intestines and mesentery over to the right side of the abdomen, raise the transverse colon toward the thorax, and divide the peritoneum covering the left side of the aorta.

The *Inferior Mesenteric Artery* supplies the descending and sigmoid flexure of the colon and the greater part of the rectum. It is smaller than the superior mesenteric, and arises from the left side of the aorta, between one and two inches above its division into the common iliacs. It passes downward to the left iliac fossa, and then descends, between the layers of the meso-rectum, into the pelvis, under the name of the *superior hæmorrhoidal artery*. It lies at first in close relation with the left side of the aorta, and then passes as the superior hæmorrhoidal in front of the left common iliac artery. Its branches are—the

Colica Sinistra.	Sigmoid.
Superior Hæmorrhoidal.	

The *colica sinistra* passes behind the peritoneum, in front of the left kidney, to reach the descending colon, and divides into two branches—an ascending branch, which inosculates with the *colica media*; and a descending branch, which anastomoses with the sigmoid artery. From the arches formed by these inosculations branches are distributed to the descending colon.

The *sigmoid artery* runs obliquely downward across the Psoas muscle to the

sigmoid flexure of the colon, and divides into branches which supply that part of the intestine, anastomosing above with the colica sinistra, and below with the superior hæmorrhoidal artery. This vessel is sometimes replaced by three or four small branches.

The **superior hæmorrhoidal artery**, the continuation of the inferior mesenteric, descends into the pelvis between the layers of the meso-rectum, crossing, in its

FIG. 371.—The inferior mesenteric and its branches.

course, the ureter and left common iliac vessels. It divides into two branches, which descend one on each side of the rectum, and about five inches from the anus break up into several small branches, which are distributed between the mucous and muscular coats of that tube, nearly as far as its lower end, anastomosing with each other, with the middle hæmorrhoidal arteries, branches of the internal iliac, and with the inferior hæmorrhoidal branches of the internal pudic.

The Suprarenal Arteries.

The **suprarenal arteries** (Fig. 367) are two small vessels which arise, one on each side of the aorta, opposite the superior mesenteric artery. They pass obliquely upward and outward, over the crura of the Diaphragm, to the under surface of the suprarenal capsules, to which they are distributed, anastomosing with capsular branches from the phrenic and renal arteries. In the adult these arteries are of small size; in the fœtus they are as large as the renal arteries.

The Renal Arteries.

The **renal arteries** are two large trunks which arise from the sides of the aorta immediately below the superior mesenteric artery. Each is directed outward across the crus of the Diaphragm, so as to form nearly a right angle with the aorta. The right is longer than the left, on account of the position of the aorta; it passes behind the inferior vena cava. The left is somewhat higher than the right. Previously to entering the kidney each artery divides into four or five branches which are distributed to its substance. At the hilum these branches lie between the renal vein and ureter, the vein being usually in front, the ureter behind. Each vessel gives off some small branches to the suprarenal capsule, the ureter, and the surrounding cellular tissue and muscles. Frequently there is a second renal artery, which is given off from the abdominal aorta at a lower level and supplies the lower portion of the kidney. It is termed the *inferior renal artery*.

The Spermatic Arteries.

The **spermatic arteries** are distributed to the testes in the male and to the ovaria in the female. They are two slender vessels, of considerable length, which arise from the front of the aorta a little below the renal arteries. Each artery passes obliquely outward and downward behind the peritoneum, resting on the Psoas muscle, the right spermatic lying in front of the inferior vena cava, the left behind the sigmoid flexure of the colon. It then crosses obliquely over the ureter and the lower part of the external iliac artery to reach the internal abdominal ring, through which it passes, and accompanies the other constituents of the spermatic cord along the inguinal canal to the scrotum, where it becomes tortuous, and divides into several branches, two or three of which accompany the vas deferens and supply the epididymis, anastomosing with the artery of the vas deferens; others pierce the back part of the tunica albuginea, and supply the substance of the testis.

The Ovarian Arteries.

The **ovarian arteries** are shorter than the spermatic, and do not pass out of the abdominal cavity. The origin and course of the first part of the artery are the same as the spermatic in the male, but on arriving at the margin of the pelvis the ovarian artery passes inward, between the two laminae of the broad ligament of the uterus, to be distributed to the ovary. One or two small branches supply the Fallopian tube; another passes on to the side of the uterus and anastomoses with the uterine arteries. Other offsets are continued along the round ligament, through the inguinal canal, to the integument of the labium and groin.

At an early period of fetal life, when the testes or ovaries lie by the side of the spine below the kidneys, the spermatic or ovarian arteries are short; but as these organs descend from the abdomen into the scrotum the arteries become gradually lengthened.

*Parietal Branches of the Abdominal Aorta.***The Phrenic Arteries.**

The **phrenic arteries** are two small vessels which present much variety in their origin. They may arise separately from the front of the aorta, immediately above the coeliac axis, or by a common trunk, which may spring either from the aorta or from the coeliac axis. Sometimes one is derived from the aorta, and the other from one of the renal arteries. In only one out of thirty-six cases examined did these arteries arise as two separate vessels from the aorta. They diverge from one another across the crura of the Diaphragm, and then pass obliquely upward and outward upon its under surface. The left phrenic passes behind the œsophagus and runs forward on the left side of the œsophageal opening. The right phrenic passes behind the inferior vena cava, and ascends along the right side of the aperture for transmitting that vein. Near the back part of the central tendon each vessel divides into two branches. The internal branch runs forward to the front of the thorax, supplying the Diaphragm and anastomosing with its fellow of

the opposite side, and with the musculo-phrenic and comes nervi phrenici, branches of the internal mammary. The external branch passes toward the side of the thorax and inosculates with the intercostal arteries. The internal branch of the right phrenic gives off a few vessels to the inferior vena cava, and the left one some branches to the œsophagus. Each vessel also sends capsular branches to the suprarenal capsule of its own side. The spleen on the left side and the liver on the right also receive a few branches from these vessels.

The Lumbar Arteries.

The lumbar arteries are analogous to the intercostal. They are usually four in number on each side, and arise from the back part of the aorta, nearly at right angles with that vessel. They pass outward and backward, around the sides of the body of the lumbar vertebra, behind the sympathetic nerve and the Psoas magnus muscle, those on the right side being covered by the inferior vena cava, and the two upper ones on each side by the crura of the Diaphragm. In the interval between the transverse processes of the vertebræ each artery divides into a dorsal and an abdominal branch.

The dorsal branch gives off, immediately after its origin, a spinal branch, which enters the spinal canal; it then continues its course backward between the transverse processes, and is distributed to the muscles and integument of the back, anastomosing with the similar branches of the adjacent lumbar arteries and with the posterior branches of the intercostal arteries.

The spinal branch enters the spinal canal through the intervertebral foramen, to be distributed to the spinal cord and its membranes and to the bodies of the vertebræ in the same manner as the lateral spinal branches from the vertebral (see page 584).

The abdominal branches pass outward, having a variable relation to the Quadratus lumborum muscle. Most frequently the first branch passes in front of the muscle and the others behind it; sometimes the order is reversed and the lowest branch passes in front of the muscle. At the outer border of the Quadratus they are continued between the abdominal muscles, anastomose with branches of the epigastric and internal mammary *in front*, the intercostals *above*, and those of the ilio-lumbar and circumflex iliac *below*.

The Sacra Media.

The Middle Sacral Artery is a small vessel about the size of a crow-quill, which arises from the back part of the aorta just at its bifurcation. It descends upon the last lumbar vertebra, and along the middle line of the front of the sacrum, to the upper part of the coccyx, where it anastomoses with the lateral sacral arteries, and terminates in a minute branch, which runs down to the situation of the body presently to be described as "Luschka's gland." From it branches arise which run through the meso-rectum to supply the posterior surface of the rectum. Other branches are given off on each side, which anastomose with the lateral sacral arteries, and send off small offsets which enter the anterior sacral foramina.

The artery is the representative of the caudal prolongation of the aorta of animals, and its lateral branches correspond to the intercostal and lumbar arteries in the dorsal and lumbar regions.

Coccygeal Gland, or Luschka's Gland.—Lying near the tip of the coccyx in a small tendinous interval formed by the union of the Levator ani muscles of each side, and just above the coccygeal attachment of the Sphincter ani, is a small conglobate body about as large as a lentil or a pea, first described by Luschka,¹ and named by him the *coccygeal gland*. Its most obvious connections are with the arteries of the part.

Structure.—It consists of a congeries of small arteries with little aneurismal dilatations derived from the middle sacral and freely communicating with each

¹ *Der Hirnanhang und die Steissdrüse des Menschen*, Berlin, 1860; *Anatomie des Menschen*, Tübingen, 1864, vol. ii, pt. 2, p. 187.

other. These vessels are enclosed in one or more layers of polyhedral granular cells, and the whole structure is invested in a capsule of connective tissue which sends in trabeculae, dividing the interior into a number of spaces in which the vessels and cells are contained. Nerves pass into this little body from the sympathetic, but their mode of termination is unknown. Macalister believes the glomerulus of vessels "consists of the condensed and convoluted metameric dorsal arteries of the caudal segments imbedded in tissue which is possibly a small persisting fragment of the neurenteric canal."

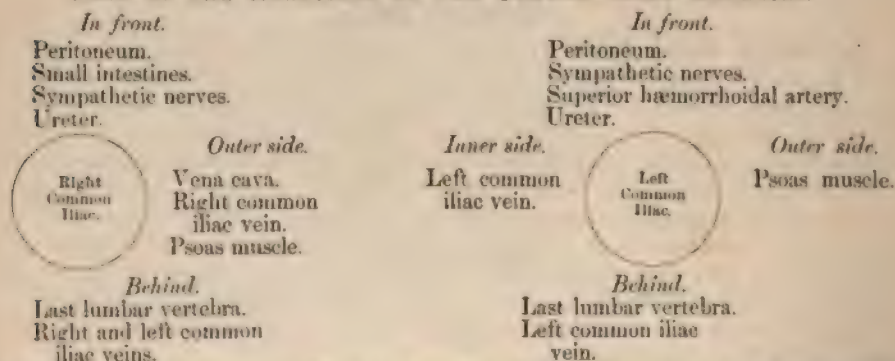

THE COMMON ILIAC ARTERIES.

The abdominal aorta divides into the two **common iliac arteries**. The bifurcation usually takes place on the left side of the body of the fourth lumbar vertebra. This point corresponds to the left side of the umbilicus, and is on a level with a line drawn from the highest point of one iliac crest to the other. The common iliac arteries are about two inches in length; diverging from the termination of the aorta, they pass downward and outward to the margin of the pelvis, and divide opposite the intervertebral substance, between the last lumbar vertebra and the sacrum into two branches, the *external* and *internal iliac arteries*, the former supplying the lower extremity; the latter, the viscera and parietes of the pelvis.

The **right common iliac** is somewhat larger than the left, and passes more obliquely across the body of the last lumbar vertebra. In front of it are the peritoneum, the small intestine, branches of the sympathetic nerve, and, at its point of division, the ureter. *Behind*, it is separated from the last lumbar vertebra by the two common iliac veins. On its *outer side*, it is in relation with the inferior vena cava and the right common iliac vein above, and the Psoas magnus muscle below.

The **left common iliac** is in relation, in front, with the peritoneum, branches of the sympathetic nerve and the superior hæmorrhoidal artery, and is crossed at its point of bifurcation by the ureter. The left common iliac vein lies partly on the inner side and partly beneath the artery; on its outer side the artery is in relation with the Psoas magnus muscle.

PLAN OF THE RELATIONS OF THE COMMON ILIAC ARTERIES.

Branches.—The common iliac arteries give off small branches to the peritoneum Psoas magnus, ureters, and the surrounding cellular tissue, and occasionally give origin to the ilio-lumbar or renal arteries.

Peculiarities.—The *point of origin* varies according to the bifurcation of the aorta. In three-fourths of a large number of cases the aorta bifurcated either upon the fourth lumbar vertebra or upon the intervertebral disk between it and the fifth, the bifurcation being, in one case out of nine below, and in one out of eleven above, this point. In ten out of every thirteen cases the vessel bifurcated within half an inch above or below the level of the crest of the ilium more frequently below than above.

The *point of division* is subject to great variety. In two-thirds of a large number of cases it was between the last lumbar vertebra and the upper border of the sacrum being above that

point in one case out of eight; and below it in one case out of six. The left common iliac artery divides lower down more frequently than the right.

The *relative length*, also, of the two common iliac arteries varies. The right common iliac was the longer in sixty-three cases, the left in fifty-two, whilst they were both equal in fifty-three. The length of the arteries varied in five-sevenths of the cases examined from an inch and a half to three inches; in about half of the remaining cases the artery was longer and in the other half shorter, the minimum length being less than half an inch, the maximum four and a half inches. In two instances the right common iliac has been found wanting, the external and internal iliacs arising directly from the aorta.

Surface Marking.—Draw a zone round the body opposite the highest part of the crest of the ilium; in this line take a point half an inch to the left of the middle line. From this

FIG. 372.—Arteries of the pelvis.

draw two lines to points midway between the anterior superior spines of the ilium and the symphysis pubis. These two diverging lines will represent the course of the common and external iliac arteries. Draw a second zone round the body corresponding to the level of the anterior superior spines of the ilium: the portion of the diverging lines between the two zones will represent the course of the common iliac artery; the portion below the lower zone, that of the external iliac artery.

Surgical Anatomy.—The application of a ligature to the common iliac artery may be required on account of aneurism or hæmorrhage implicating the external or internal iliacs. The artery may be tied by one or two incisions: 1, an anterior or iliac incision, by which the vessel is approached more directly from the front; and 2, a posterior abdominal or lumbar incision, by which the vessel is reached from behind. If the surgeon select the iliac region, a curved incision, from five to eight inches in length according to the amount of fat, is made, commencing just outside the middle of Poupart's ligament and a finger's breadth above it, and carried outward toward the anterior superior iliac spine, then upward toward the ribs, and finally curving inward

toward the umbilicus. The abdominal muscles and transversalis fascia are divided, and the peritoneum raised upward and inward until the Psoas is reached. The artery will be found on the inner side of this muscle, and is to be cleared with a director, especial care being taken on the right side, as here the common iliac veins lie behind the artery. The aneurism needle is to be passed from within outward. But if the aneurismal tumor should extend high up in the abdomen, along the external iliac, it is better to select the posterior or lumbar, by making an incision partly in the abdomen, partly in the loin. The incision is commenced at the anterior extremity of the last rib, proceeding directly downward to the ilium; it is then curved forward along the crest of the ilium and a little above it to the anterior superior spine of that bone. The abdominal muscles having been cautiously divided in succession, the transversalis fascia must be carefully cut through, and the peritoneum, together with the ureter, separated from the artery and pushed aside; the sacro-iliac articulation must then be felt for, and upon it the vessel will be felt pulsating, and may be fully exposed in close connection with its accompanying vein. On the right side both common iliac veins, as well as the inferior vena cava, are in close connection with the artery, and must be carefully avoided. On the left side the vein usually lies on the inner side and behind the artery; but it occasionally happens that the two common iliac veins are joined on the left instead of the right side, which would add much to the difficulty of an operation in such a case. The common iliac artery may be so short that danger may be apprehended from secondary hæmorrhage if a ligature is applied to it. It would be preferable, in such a case, to tie both the external and internal iliacs near their origin.

Collateral Circulation.—The principal agents in carrying on the collateral circulation after the application of a ligature to the common iliac are—the anastomoses of the hæmorrhoidal branches of the internal iliac with the superior hæmorrhoidal from the inferior mesenteric; the anastomoses of the uterine and ovarian arteries and of the vesical arteries of opposite sides; of the lateral sacral with the middle sacral artery; of the epigastric with the internal mammary, inferior intercostal, and lumbar arteries; of the circumflex iliac with the lumbar arteries; of the ilio-lumbar with the last lumbar artery; of the obturator artery, by means of its pubic branch, with the vessel of the opposite side and with the deep epigastric.

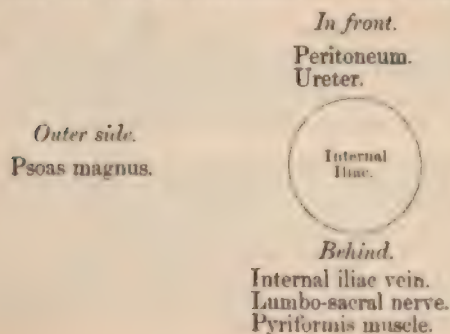

Compression of the Common Iliac Arteries.—The common iliac arteries are most efficiently compressed by Davy's lever. The instrument consists of a gum-elastic tube about two feet long, in which fits a round wooden "lever" considerably longer than the tube. A small quantity of olive oil having been injected into the rectum, the gum-elastic tube, softened in hot water, is passed into the bowel sufficiently far to permit its pressing upon the common iliac artery as it lies in the groove between the last lumbar vertebra and the Psoas muscle. The wooden lever is then inserted into the tube, and the projecting end carried toward the opposite thigh and raised, when it acts as a lever of the first order, the anus being the fulcrum. In cases where the meso-rectum is abnormally short it may be impossible, without unjustifiable force, to compress the artery on the right side.

Internal Iliac Artery (Fig. 372).

The internal iliac artery supplies the walls and viscera of the pelvis, the generative organs, and inner side of the thigh. It is a short, thick vessel, smaller in the adult than the external iliac, and about an inch and a half in length. It arises at the point of bifurcation of the common iliac, and, passing downward to the upper margin of the great sacro-sciatic foramen, divides into two large trunks, an *anterior* and *posterior*; from its point of bifurcation a partially obliterated cord, the *hypogastric artery*, extends forward to the bladder.

Relations.—*In front*, with the ureter, which separates it from the peritoneum. *Behind*, with the internal iliac vein, the lumbo-sacral nerve, and Pyriformis muscle. By its *outer side*, near its origin, with the Psoas magnus muscle.

PLAN OF THE RELATIONS OF THE INTERNAL ILIAC ARTERY.

In the *fœtus* the internal iliac artery (*hypogastric*) is twice as large as the external iliac, and appears to be the continuation of the common iliac. Instead of dipping into the pelvis, it passes forward to the bladder, and ascends along the sides of that viscus to its summit, to which it gives branches; it then passes upward along the back part of the anterior wall of the abdomen to the umbilicus, converging toward its fellow of the opposite side. Having passed through the umbilical opening, the two arteries twine round the umbilical vein, forming with it the umbilical cord, and ultimately ramify in the placenta. The portion of the vessel within the abdomen is called the *hypogastric artery*, and that external to that cavity, the *umbilical artery*.

At birth, when the placental circulation ceases, the upper portion of the hypogastric artery, extending from the summit of the bladder to the umbilicus, contracts, and ultimately dwindles to a solid fibrous cord; but the lower portion, extending from its origin (in what is now the internal iliac artery) for about an inch and a half to the wall of the bladder, and thence to the summit of that organ, is not totally impervious, though it becomes considerably reduced in size, and serves to convey blood to the bladder under the name of the *superior vesical artery*.

Peculiarities as regards Length.—In two-thirds of a large number of cases the length of the internal iliac varied between an inch and an inch and a half; in the remaining third it was more frequently longer than shorter, the maximum length being three inches, the minimum half an inch.

The lengths of the common and internal iliac arteries bear an inverse proportion to each other, the internal iliac artery being long when the common iliac is short, and *vice versa*.

As regards its Place of Division.—The place of division of the internal iliac varies between the upper margin of the sacrum and the upper border of the sacro-sciatic foramen.

The arteries of the two sides in a series of cases often differed in length, but neither seemed constantly to exceed the other.

Surgical Anatomy.—The application of a ligature to the internal iliac artery may be required in cases of aneurism or hæmorrhage affecting one of its branches. The vessel may be secured by making an incision through the abdominal parietes in the iliac region in a direction and to an extent similar to that for securing the common iliac; the transversalis fascia having been cautiously divided, and the peritoneum pushed inward from the iliac fossa toward the pelvis, the finger may feel the pulsation of the external iliac at the bottom of the wound, and by tracing this vessel upward the internal iliac is arrived at, opposite the sacro-iliac articulation. It should be remembered that the vein lies behind and on the right side, a little external to the artery, and in close contact with it; the ureter and peritoneum, which lie in front, must also be avoided. The degree of facility in applying a ligature to this vessel will mainly depend upon its length. It has been seen that in the great majority of the cases examined the artery was short, varying from an inch to an inch and a half; in these cases the artery is deeply seated in the pelvis; when, on the contrary, the vessel is longer, it is found partly above that cavity. If the artery is very short, as occasionally happens, it would be preferable to apply a ligature to the common iliac or upon the external and internal iliaes at their origin.

Probably a better method of tying the internal iliac artery is by an abdominal section in the median line and reaching the vessel through the peritoneal cavity. This plan has been advocated by Dennis of New York on the following grounds: (1) It no way increases the danger of the operation; (2) it prevents a series of accidents which have occurred during ligature of the artery by the older methods; (3) it enables the surgeon to ascertain the exact extent of disease in the main arterial trunk, and select his spot for the application of the ligature; and (4) it occupies much less time.

Collateral Circulation.—In Professor Owen's dissection of a case in which the internal iliac artery had been tied by Stevens ten years before death for aneurism of the sciatic artery, the internal iliac was found impervious for about an inch above the point where the ligature had been applied, but the obliteration did not extend to the origin of the external iliac, as the ilio-lumbar artery arose just above this point. Below the point of obliteration the artery resumed its natural diameter, and continued so for half an inch, the obturator, lateral sacral, and gluteal arising in succession from the latter portion. The obturator artery was entirely obliterated. The lateral sacral artery was as large as a crow's quill, and had a very free anastomosis with the artery of the opposite side and with the middle sacral artery. The sciatic artery was entirely obliterated as far as its point of connection with the aneurismal tumor, but on the distal side of the sac it was continued down along the back of the thigh nearly as large in size as the femoral, being pervious about an inch below the sac by receiving an anastomosing vessel from the profunda. The circulation was carried on by the anastomoses of the uterine and ovarian arteries;

Lateral Sacral.
Gluteal.

The **superior vesical** is that part of the foetal hypogastric artery which remains pervious after birth. It extends to the side of the bladder, distributing numerous branches to the apex and body of the organ. From one of these a slender vessel is derived which accompanies the vas deferens in its course to the testis, where it anastomoses with the spermatic artery. This is the *artery of the vas deferens*. Other branches supply the ureter.

The **middle vesical**, usually a branch of the superior, is distributed to the base of the bladder and under surface of the vesiculæ seminales.

The **inferior vesical** arises from the anterior division of the internal iliac, frequently in common with the middle hæmorrhoidal, and is distributed to the base of the bladder, the prostate gland, and vesiculæ seminales. The branches distributed to the prostate communicate with the corresponding vessel of the opposite side.

The **middle hæmorrhoidal artery** usually arises together with the preceding vessel. It supplies the rectum, anastomosing with the other hæmorrhoidal arteries.

The **uterine artery** passes inward from the anterior trunk of the internal iliac to the neck of the uterus. Ascending, in a tortuous course on the side of this viscus, between the layers of the broad ligament, it distributes branches to its substance, anastomosing, near its termination, with a branch from the ovarian artery. Branches from this vessel are also distributed to the bladder and ureter.

The **vaginal artery** is analogous to the inferior vesical in the male; it descends upon the vagina, supplying its mucous membrane, and sending branches to the neck of the bladder and contiguous part of the rectum.

The **Obturator Artery** usually arises from the anterior trunk of the internal iliac, frequently from the posterior. It passes forward, below the brim of the pelvis, to the upper part of the obturator foramen, and, escaping from the pelvic cavity through a short canal formed by a groove on the under surface of the horizontal ramus of the os pubis and the arched border of the obturator membrane, it divides into an internal and external branch. In the pelvic cavity this vessel lies upon the pelvic fascia, beneath the peritoneum, and a little below the obturator nerve.

Branches.—*Within the pelvis*, the obturator artery gives off an *iliac branch* to the iliac fossa, which supplies the bone and the Iliacus muscle, and anastomoses with the ilio-lumbar artery; a *vesical branch*, which runs backward to supply the bladder; and a *pubic branch*, which is given off from the vessel just before it leaves the pelvic cavity. This branch ascends upon the back of the os pubis,

communicating with offsets from the deep epigastric artery and with the corresponding vessel of the opposite side. This branch is placed on the inner side of the femoral ring. *External to the pelvis*, the obturator artery divides into an *internal* and an *external branch*, which are deeply situated beneath the Obturator externus muscle.

The **internal branch** curves downward along the inner margin of the obturator foramen, distributing branches to the Obturator externus muscle, Pectineus, Adductors, and Gracilis, and anastomoses with the external branch and with the internal circumflex artery.

The **external branch** curves round the outer margin of the foramen to the space between the Gemellus inferior and Quadratus femoris, where it anastomoses with the sciatic artery. It supplies the Obturator muscles, anastomoses, as it passes backward, with the internal branch and with the internal circumflex, and

FIG. 373.—Variations in origin and course of obturator artery.

sends a branch to the hip-joint through the cotyloid notch, which ramifies on the round ligament as far as the head of the femur.

Peculiarities.—In two out of every three cases the obturator arises from the internal iliac: in one case in three and a half from the epigastric; and in about one in seventy-two cases by two roots from both vessels. It arises in about the same proportion from the external iliac artery. The origin of the obturator from the epigastric is not commonly found on both sides of the same body.

When the obturator artery arises at the front of the pelvis from the epigastric, it descends almost vertically to the upper part of the obturator foramen. The artery in this course usually lies in contact with the external iliac vein and on the outer side of the femoral ring (Fig. 373, A); in such cases it would not be endangered in the operation for femoral hernia. Occasionally, however, it curves inward along the free margin of Gimbernat's ligament (Fig. 373, B), and under such circumstances would almost completely encircle the neck of a hernial sac (supposing a hernia to exist in such a case), and would be in great danger of being wounded if an operation was performed.

The **internal pudic** is the smaller of the two terminal branches of the anterior trunk of the internal iliac, and supplies the external organs of generation. Though the course of the artery is the same in the two sexes, the vessel is much smaller in the female than in the male, and the distribution of its branches somewhat different. The description of its arrangement in the male will first be given, and subsequently the differences which it presents in the female will be mentioned.

The **Internal Pudic Artery in the Male** passes downward and outward to the lower border of the great sacro-sciatic foramen, and emerges from the pelvis between the Pyriformis and Coccygeus muscles: it then crosses the spine of the ischium and re-enters the pelvis through the lesser sacro-sciatic foramen. The artery now crosses the Obturator internus muscle along the outer wall of the ischio-rectal fossa, being situated about an inch and a half above the lower margin of the ischial tuberosity. It is here contained in a sheath of the obturator fascia, and gradually approaches the margin of the ramus of the ischium, along which it passes forward and upward, pierces the posterior layer of the deep perineal fascia, and runs forward along the inner margin of the ramus of the os pubis; finally, it perforates the anterior layer of the deep perineal fascia and divides into its two

terminal branches, the *dorsal artery of the penis* and the *artery of the corpus cavernosum*.

Relations.—In the first part of its course, within the pelvis, it lies in front of the *Pyriformis* muscle and *sacral plexus* of nerves, and on the outer side of the *rectum* (on the left side). As it crosses the spine of the *ischium* it is covered by

FIG. 374.—The internal pudic artery and its branches in the male.

the *Gluteus maximus*. In the pelvis it lies on the outer side of the *ischio-rectal fossa*, upon the surface of the *Obturator internus* muscle, contained in a fibrous canal formed by the *obturator fascia* and the *falciform process* of the *great sacro-sciatic ligament*. It is accompanied by the *pudic veins* and the *internal pudic nerve*.

Peculiarities.—The internal pudic is sometimes smaller than usual, or fails to give off one or two of its usual branches; in such cases the deficiency is supplied by branches derived from an additional vessel, the *accessory pudic*, which generally arises from the internal pudic artery before its exit from the *great sacro-sciatic foramen*. It passes forward along the lower part of the *bladder* and across the side of the *prostate gland* to the root of the *penis*, where it perforates the *triangular ligament* and gives off the branches usually derived from the pudic artery. The deficiency most frequently met with is that in which the internal pudic ends as the artery of the *bulb*, the artery of the *corpus cavernosum* and *arteria dorsalis penis* being derived from the accessory pudic. Or the pudic may terminate as the *superficial perineal*, the artery of the *bulb* being derived, with the other two branches, from the accessory vessel.

Surgical Anatomy.—The relation of the accessory pudic to the *prostate gland* and *urethra* is of the greatest interest in a surgical point of view, as this vessel is in danger of being wounded in the lateral operation of *lithotomy*. The student should also study the position of the internal pudic artery and its branches, when running a normal course, with regard to the same operation. The *superficial* and the *transverse perineal* arteries are, of necessity, divided in this operation, but the *hemorrhage* from these vessels is seldom excessive; should a *ligature* be required, it can readily be applied on account of their superficial position. The artery of the *bulb* may be divided if the incision be carried too far forward, and injury of this vessel may be attended with serious or even fatal consequences. The main trunk of the internal pudic artery may be wounded if the incision be carried too far outward; but, being bound down by the strong *obturator fascia* and under cover of the *ramus* of the *ischium*, the accident is not very likely to occur unless the vessel runs an anomalous course.

Branches.—The branches of the internal pudic artery are—

Muscular.	Transverse Perineal.
Inferior Hæmorrhoidal.	Artery of the Bulb.
Superficial Perineal.	Artery of the Corpus Cavernosum.
Dorsal Artery of the Penis.	

The **muscular branches** consist of two sets—one given off in the pelvis, the other as the vessel crosses the ischial spine. The former are several small offsets which supply the Levator ani, the Obturator internus, the Pyriformis, and the Coccygeus muscles. The branches given off outside the pelvis are distributed to the adjacent part of the Gluteus maximus and External rotator muscles. They anastomose with branches of the sciatic artery.

The **inferior hæmorrhoidal** are two or three small arteries which arise from the internal pudic as it passes above the tuberosity of the ischium. Crossing the ischio-rectal fossa, they are distributed to the muscles and integument of the anal region.

The **superficial perineal artery** supplies the scrotum and muscles and integument of the perinæum. It arises from the internal pudic in front of the preceding branches, and turns upward, crossing either over or under the Transversus perinæi muscle, and runs forward, parallel to the pubic arch, in the interspace between the Accelerator urinæ and Erector penis muscles, both of which it supplies, and is finally distributed to the skin and dartos of the scrotum. In its passage through the perinæum it lies beneath the superficial perineal fascia.

The **transverse perineal** is a small branch which arises either from the internal pudic or from the superficial perineal artery as it crosses the Transversus perinæi muscle. It runs transversely inward along the cutaneous surface of the Transversus perinæi muscle, which it supplies, as well as the structures between the anus and bulb of the urethra, and anastomoses with the one of the opposite side.

The **artery of the bulb** is a large but very short vessel which arises from the internal pudic between the two layers of the deep perineal fascia, and, passing nearly transversely inward, pierces the bulb of the urethra, in which it ramifies. It gives off a small branch which descends to supply Cowper's gland.

Surgical Anatomy.—This artery is of considerable importance in a surgical point of view, as it is in danger of being wounded in the lateral operation of lithotomy—an accident usually attended in the adult with alarming hæmorrhage. The vessel is sometimes very small, occasionally wanting, or even double. It sometimes arises from the internal pudic earlier than usual, and crosses the perineum to reach the back part of the bulb. In such a case the vessel could hardly fail to be wounded in the performance of the lateral operation of lithotomy. If, on the contrary, it should arise from an accessory pudic, it lies more forward than usual and is out of danger in the operation.

The **artery of the corpus cavernosum**, one of the terminal branches of the internal pudic, arises from that vessel while it is situated between the crus penis and the ramus of the os pubis; piercing the crus penis obliquely, it runs forward in the centre of the corpus cavernosum, to which its branches are distributed.

The **dorsal artery of the penis** ascends between the crus and pubic symphysis, and, piercing the suspensory ligament, runs forward on the dorsum of the penis to the glans, where it divides into two branches which supply the glans and prepuce. On the dorsum of the penis it lies immediately beneath the integument, parallel with the dorsal vein and the corresponding artery of the opposite side. It supplies the integument and fibrous sheath of the corpus cavernosum, sending branches through the sheath to anastomose with the preceding vessel.

The **Internal Pudic Artery in the Female** is smaller than in the male. Its origin and course are similar, and there is considerable analogy in the distribution of its branches. The superficial artery supplies the labia pudendi; the artery of the bulb supplies the bulbi vestibuli and the erectile tissue of the vagina; the artery of the corpus cavernosum supplies the cavernous body of the clitoris; and the arteria dorsalis clitoridis supplies the dorsum of that organ, and terminates in the glans and in the membranous fold corresponding to the prepuce of the male.

The **Sciatic Artery** (Fig. 375), the larger of the two terminal branches of the anterior trunk of the internal iliac, is distributed to the muscles at the back of the pelvis. It passes down to the lower part of the great sacro-sciatic foramen behind the internal pudic artery, resting on the sacral plexus of nerves and Piriformis muscle, and escapes from the pelvis through this foramen between the Piriformis and Coccygeus. It then descends in the interval between the trochanter major and

tuberosity of the ischium, accompanied by the sciatic nerves, and covered by the Gluteus maximus, and is continued down the back of the thigh supplying the skin, and anastomosing with branches of the perforating arteries.

Within the pelvis it distributes branches to the Piriformis, Coccygeus, and Levator ani muscles; some hæmorrhoidal branches, which supply the rectum, and occasionally take the place of the middle hæmorrhoidal artery; and vesical branches to the base and neck of the bladder, vesiculæ seminales, and prostate gland. *External to the pelvis* it gives off the following branches:

Coccygeal.
Inferior Gluteal.
Comes Nervi Ischiadici.
Muscular.
Articular.

The **coccygeal branch** runs inward, pierces the great sacro-sciatic ligament, and supplies the Gluteus maximus, the integument, and other structures on the back of the coccyx.

The **inferior gluteal branches**, three or four in number, supply the Gluteus maximus muscle, anastomosing with the gluteal artery in the substance of the muscle.

The **comes nervi ischiadici** is a long, slender vessel which accompanies the great sciatic nerve for a short distance; it then penetrates it and runs in its substance to the lower part of the thigh.

FIG. 375.—The arteries of the gluteal and posterior femoral regions.

The **muscular branches** supply the muscles on the back part of the hip, anastomosing with the gluteal, external branch of the obturator, internal and external circumflex, and superior perforating arteries.

Some **articular branches** are distributed to the capsule of the hip-joint.

The **Ilio-lumbar Artery**, given off from the posterior trunk of the internal

iliac, turns upward and outward between the obturator nerve and lumbo-sacral cord, to the inner margin of the Psoas muscle, behind which it divides into a lumbar and an iliac branch.

The **lumbar branch** supplies the Psoas and Quadratus lumborum muscles, anastomosing with the last lumbar artery, and sends a small spinal branch through the intervertebral foramen, between the last lumbar vertebra and the sacrum, into the spinal canal, to supply the spinal cord and its membranes.

The **iliac branch** descends to supply the Iliacus muscle; some offsets, running between the muscle and the bone, anastomose with the iliac branch of the obturator; one of these enters an oblique canal to supply the diploë, whilst others run along the crest of the ilium, distributing branches to the Gluteal and Abdominal muscles, and anastomose in their course with the gluteal, circumflex iliac, and external circumflex arteries.

The **Lateral Sacral Arteries** (Fig. 372) are usually two in number on each side, superior and inferior.

The **superior**, which is of large size, passes inward, and, after anastomosing with branches from the middle sacral, enters the first or second sacral foramen, is distributed to the contents of the sacral canal in the same manner as the lateral spinal branches from the vertebral, and, escaping by the corresponding posterior sacral foramen, supplies the skin and muscles on the dorsum of the sacrum, anastomosing with the gluteal.

The **inferior** passes obliquely across the front of the Piriformis muscle and sacral nerves to the inner side of the anterior sacral foramina, descends on the front of the sacrum, and anastomoses over the coccyx with the sacra media and opposite lateral sacral arteries. In its course it gives off branches which enter the anterior sacral foramina; these, after giving off branches to be distributed to the contents of the sacral canal in the same manner as the lateral spinal branches from the vertebral, escape by the posterior sacral foramina, and are distributed to the muscles and skin on the dorsal surface of the sacrum, anastomosing with the gluteal.

The **Gluteal Artery** is the largest branch of the internal iliac, and appears to be the continuation of the posterior division of that vessel. It is a short, thick trunk, which passes out of the pelvis above the upper border of the Piriformis muscle, and immediately divides into a *superficial* and *deep branch*. Within the pelvis it gives off a few muscular branches to the Iliacus, Piriformis, and Obturator internus, and, just previous to quitting that cavity, a nutrient artery, which enters the ilium.

The **superficial branch** passes beneath the Gluteus maximus and divides into numerous branches, some of which supply that muscle, whilst others perforate its tendinous origin, and supply the integument covering the posterior surface of the sacrum, anastomosing with the posterior branches of the sacral arteries.

The **deep branch** runs between the Gluteus medius and minimus, and subdivides into two. Of these, the superior division, continuing the original course of the vessel, passes along the upper border of the Gluteus minimus to the anterior superior spine of the ilium, anastomosing with the circumflex iliac and ascending branches of the external circumflex artery. The inferior division crosses the Gluteus minimus obliquely to the trochanter major, distributing branches to the Glutei muscles, and inosculates with the external circumflex artery. Some branches pierce the Gluteus minimus to supply the hip-joint.

Surface Marking.—The position of the three main branches of the internal iliac, the sciatic, internal pudic, and gluteal, which may occasionally be the object of surgical interference, is indicated on the surface in the following way: A line is to be drawn from the posterior superior iliac spine to the posterior superior angle of the great trochanter, with the limb slightly flexed and rotated inward: the point of emergence of the *gluteal artery* from the upper part of the sciatic notch will correspond with the junction of the upper with the middle third of this line. A second line is to be drawn from the same point to the middle of the tuberosity of the ischium; the junction of the lower with the middle third marks the point of emergence of the *sciatic* and *pudic arteries* from the great sciatic notch.

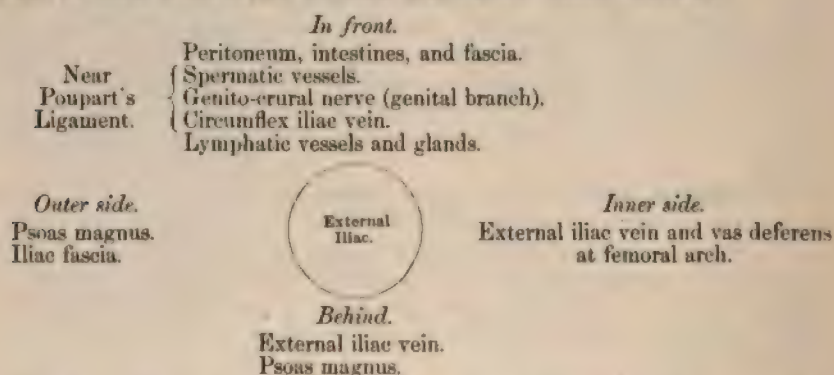

Surgical Anatomy.—Any of these three vessels may require ligaturing for a wound or for aneurism, which is generally traumatic, and the operation may be performed by an incision, three or four inches long, in the direction of the fibres of the Gluteus maximus muscle, the middle of the cut corresponding to the point indicating their respective positions.

The External Iliac Artery (Fig. 372).

The **external iliac artery** is larger in the adult than the internal iliac, and passes obliquely downward and outward along the inner border of the Psoas muscle, from the bifurcation of the common iliac to Poupart's ligament, where it enters the thigh and becomes the femoral artery.

Relations.—*In front*, with the peritoneum, subperitoneal areolar tissue, the intestines, and a thin layer of fascia derived from the iliac fascia, which surrounds the artery and vein. At its origin it is occasionally crossed by the ureter. The spermatic vessels descend for some distance upon it near its termination, and it is crossed in this situation by the genital branch of the genito-crural nerve and the circumflex iliac vein; the vas deferens curves down along its inner side. *Behind*, it is in relation with the external iliac vein, which, at Poupart's ligament, lies at its inner side; on the left side the vein is altogether internal to the artery. *Externally*, it rests against the Psoas muscle, from which it is separated by the iliac fascia. The artery rests upon this muscle, near Poupart's ligament. Numerous lymphatic vessels and glands are found lying on the front and inner side of the vessel.

PLAN OF THE RELATIONS OF THE EXTERNAL ILIAC ARTERY.

Surface Marking.—The surface line indicating the course of the external iliac artery has been already given (see page 621).

Surgical Anatomy.—The application of a ligature to the external iliac may be required in cases of aneurism of the femoral artery or for a wound of the artery. This vessel may be secured in any part of its course, excepting near its upper end, which is to be avoided on account of the proximity of the great stream of blood in the internal iliac, and near its lower end, which should also be avoided, on account of the proximity of the epigastric and circumflex iliac vessels. One of the chief points in the performance of the operation is to secure the vessel without injury to the peritoneum. The patient having been placed in the recumbent position, an incision should be made, commencing below at a point about three-quarters of an inch above Poupart's ligament, and a little external to its middle, and running upward and outward, parallel to Poupart's ligament, to a point above the anterior superior spine of the ilium. When the artery is deeply seated more room will be required, and may be obtained by curving the incision from the point last named inward toward the umbilicus for a short distance, or, if the lower part of the artery is to be reached, the surgeon may adopt the plan advocated by Sir Astley Cooper, by making an incision close to Poupart's ligament, from about half an inch outside of the external abdominal ring to one inch internal to the anterior superior spine of the ilium. This incision, being made in the course of the fibres of the aponeurosis of the external oblique, is less likely to be followed by a ventral hernia, but there is danger of wounding the epigastric artery. Abernethy, who first tied this artery, made his incision in the course of the vessel. The abdominal muscles and transversalis fascia having been cautiously divided, the peritoneum should be separated from the iliac fossa and raised toward the pelvis; and on introducing the finger to the bottom of the wound the artery may be felt pulsating along the inner border of the Psoas muscle. The external iliac vein is generally found on the inner side of the artery,

and must be cautiously separated from it by the finger-nail or handle of the knife, and the aneurism needle should be introduced on the inner side, between the artery and the vein.

Ligature of the external iliac artery has recently been performed in three or more cases by a transperitoneal method. An incision four inches in length is made in the semilunar line, commencing about an inch below the umbilicus and carried through the abdominal wall into the peritoneal cavity. The intestines are then pushed upward and held out of the way by a broad abdominal retractor, and an incision made through the peritoneum at the margin of the pelvis in the course of the artery, and the vessel secured in any part of its course which may seem desirable to the operator. The advantages of this operation appear to be that if it is found necessary the common iliac artery can be ligatured instead of the external iliac without extension or modification of the incision; and secondly, that the vessel can be ligatured without in any way interfering with the coverings of the sac. Possibly a disadvantage may exist in the greater risk of hernia after this method.

Collateral Circulation.—The principal anastomoses in carrying on the collateral circulation, after the application of a ligature to the external iliac, are—the ilio-lumbar with the circumflex iliac; the gluteal with the external circumflex; the obturator with the internal circumflex; the sciatic with the superior perforating and circumflex branches of the profunda artery; and the internal pudic with the external pudic. When the obturator arises from the epigastric, it is supplied with blood by branches, either from the internal iliac, the lateral sacral, or the internal pudic. The epigastric receives its supply from the internal mammary and inferior intercostal arteries, and from the internal iliac by the anastomoses of its branches with the obturator.

In the dissection of a limb eighteen years after the successful ligature of the external iliac artery by Sir A. Cooper, which is to be found in *Guy's Hospital Reports*, vol. i. p. 50, the anastomosing branches are described in three sets: *An anterior set.*—1, a very large branch from the ilio-lumbar artery to the circumflex iliac; 2, another branch from the ilio-lumbar, joined by one from the obturator, and breaking up into numerous tortuous branches to anastomose with the external circumflex; 3, two other branches from the obturator, which passed over the brim of the pelvis, communicated with the epigastric, and then broke up into a plexus to anastomose with the internal circumflex. *An internal set.*—Branches given off from the obturator, after quitting the pelvis, which ramified among the adductor muscles on the inner side of the hip-joint, and joined most freely with branches of the internal circumflex. *A posterior set.*—1, three large branches from the gluteal to the external circumflex; 2, several branches from the sciatic around the great sciatic notch to the internal and external circumflex, and the perforating branches of the profunda.

Branches.—Besides several small branches to the Psoas muscle and the neighboring lymphatic glands, the external iliac gives off two branches of considerable size—the

Deep Epigastric and Deep Circumflex Iliac.

The **Deep Epigastric Artery** arises from the external iliac a few lines above Poupart's ligament. It at first descends to reach this ligament, and then ascends obliquely along the inner margin of the internal abdominal ring, lying between the transversalis fascia and peritoneum, and, continuing its course upward, it pierces the transversalis fascia, and, passing over the semilunar fold of Douglas, enters the sheath of the Rectus muscle. It then ascends on the posterior surface of the muscle, and finally divides into numerous branches, which anastomose, above the umbilicus, with the terminal branches of the internal mammary and inferior intercostal arteries. The deep epigastric artery bears a very important relation to the internal abdominal ring as it passes obliquely upward and inward from its origin from the external iliac. In this part of its course it lies along the lower and inner margin of the ring and beneath the commencement of the spermatic cord. As it winds round the internal abdominal ring it is crossed by the vas deferens in the male and the round ligament in the female.

Branches.—The branches of this vessel are the following: The *cremasteric*, which accompanies the spermatic cord, and supplies the Cremaster muscle and other coverings of the cord, anastomosing with the spermatic artery; a *pubic branch*, which runs along Poupart's ligament, and then descends behind the pubes to the inner side of the femoral ring, and anastomoses with offsets from the obturator artery; *muscular branches*, some of which are distributed to the abdominal muscles and peritoneum, anastomosing with the lumbar and circumflex iliac arteries; others perforate the tendon of the External oblique, and supply the integument, anastomosing with branches of the superficial epigastric.

Peculiarities.—The origin of the epigastric may take place from any part of the external iliac between Poupart's ligament and two inches and a half above it, or it may arise below this ligament, from the femoral or from the deep femoral.

Union with Branches.—It frequently arises from the external iliac by a common trunk with the obturator. Sometimes the epigastric arises from the obturator, the latter vessel being furnished by the internal iliac, or the epigastric may be formed of two branches, one derived from the external iliac, the other from the internal iliac.

Surgical Anatomy.—The deep epigastric artery follows a line drawn from the middle of Poupart's ligament toward the umbilicus; but shortly after this line crosses the linea semilunaris the direction changes, and the course of the vessel is directly upward in the line of junction of the inner third with the outer two-thirds of the Rectus muscle. It has important surgical relations, in addition to the fact that it is one of the principal means, through its anastomosis with the internal mammary, in establishing the collateral circulation after ligature of either the common or external iliac arteries. It lies close to the internal abdominal ring, and is therefore *internal* to an oblique inguinal hernia, but *external* to a direct inguinal hernia, as it emerges from the abdomen. It forms the outer boundary of Hesselbach's triangle. It is in close relationship with the spermatic cord, which lies in front of it in the inguinal canal, separated only by the transversalis fascia. The vas deferens hooks round its outer side.

The **Deep Circumflex Iliac Artery** arises from the outer side of the external iliac nearly opposite the epigastric artery. It ascends obliquely outward behind Poupart's ligament, contained in a fibrous sheath formed by the junction of the transversalis and iliac fasciæ, to the anterior superior spinous process of the ilium. It then runs along the inner surface of the crest of the ilium to about its middle, where it pierces the Transversalis, and runs backward between that muscle and the Internal oblique, to anastomose with the ilio-lumbar and gluteal arteries. Opposite the anterior superior spine of the ilium it gives off a large branch, which ascends between the Internal oblique and Transversalis muscles, supplying them, and anastomosing with the lumbar and epigastric arteries.

ARTERIES OF THE LOWER EXTREMITY.

The Femoral Artery (Fig. 376).

The **femoral artery** is the continuation of the external iliac. It commences immediately behind Poupart's ligament, midway between the anterior superior spine of the ilium and the symphysis pubis, and, passing down the fore part and inner side of the thigh, terminates at the opening in the Adductor magnus, at the junction of the middle with the lower third of the thigh, where it becomes the popliteal artery. The vessel, at the upper part of thigh, lies a little internal to the head of the femur; in the lower part of its course, on the inner side of the shaft of the bone, and between these two parts the vessel is far away from the bone. In the upper third of the thigh it is contained in a triangular space called Scarpa's triangle. In the middle third of the thigh it is contained in an aponeurotic canal called Hunter's canal.

Scarpa's Triangle.—Scarpa's triangle corresponds to the depression seen immediately below the fold of the groin. It is a triangular space, the apex of which is directed downward, and the sides formed externally by the Sartorius, internally by the Adductor longus, and above by Poupart's ligament. The floor of the space is formed from without inward by the Iliacus, Psoas, Pectineus, a small part of the Adductor brevis and the Adductor longus muscles; and it is divided into two nearly equal parts by the femoral vessels, which extend from the middle of its base to its apex, the artery giving off in this situation its cutaneous and profunda branches, the vein receiving the deep femoral and internal saphenous. On the outer side of the femoral artery is the anterior crural nerve dividing into its branches. Besides the vessels and nerves, this space contains some fat and lymphatics.

Hunter's Canal.—This is the aponeurotic space in the middle third of the thigh, extending from the apex of Scarpa's triangle to the femoral opening in the Adductor magnus muscle. It is bounded, externally, by the Vastus internus; internally, by the Adductor longus and magnus muscles; and covered in by a strong aponeurosis which extends transversely from the Vastus internus, across

the femoral vessels to the Adductor longus and magnus muscles, lying on which aponeurosis is the Sartorius muscle. It contains the femoral artery and vein enclosed in their own sheath of areolar tissue, the vein being behind and on the outer side of the artery, and the internal or long saphenous nerve lying on the outer side of the vessels.

For convenience of description, and also in reference to its surgical anatomy, the femoral artery is divided into a short trunk, about an inch and a half or two inches long, which is known as the *common femoral artery*, and the remainder of the vessel, which is known as the *superficial femoral*, to distinguish it from the deep femoral (*profunda femoris*), which is a large branch given off from the common femoral at its termination, and which by its derivation from the parent trunk marks the commencement of the superficial femoral artery.

The **common femoral artery** is very superficial, being covered by the skin and superficial fascia, superficial inguinal lymphatic glands, the iliac portion of the fascia lata, and the prolongation downward of the Transversalis fascia, which forms the sheath of the vessels. It has in front of it filaments from the crural branch of the genito-crural nerve, the superficial circumflex iliac vein, and occasionally the superficial epigastric vein. It rests on the inner margin of the Psoas muscle, which separates it from the capsular ligament of the hip-joint, and a little lower on the Pectineus muscle; and crossing behind it is the branch to the Pectineus from the anterior crural nerve. Separating the artery from the Psoas and Pectineus muscles is the pubic portion of the fascia lata and the prolongation from the fascia covering the Iliacus muscle, which forms the posterior layer of the sheath of the vessels. The anterior crural nerve lies about half an inch to the outer side of the common femoral artery, lying between the Psoas and Iliacus muscles. To the inner side of the artery is the femoral vein, between the margins of the Pectineus and Psoas muscles. The two vessels are enclosed in a strong fibrous sheath formed by the proper sheath of the vessels strengthened by the fascia lata (see page 509); the

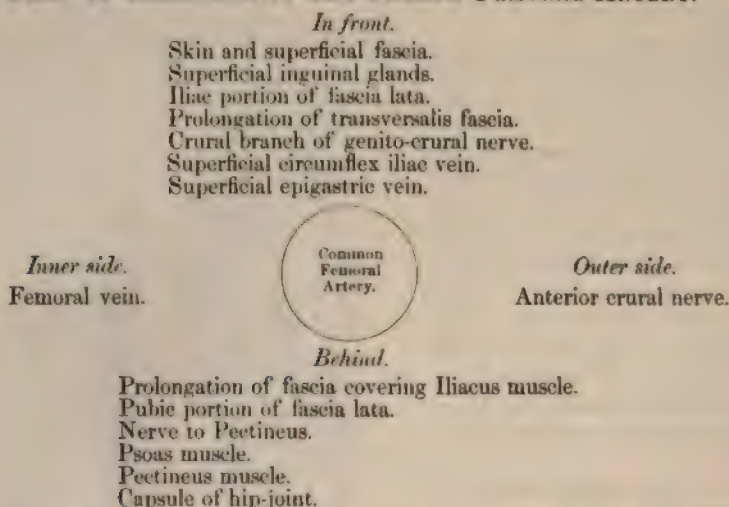

FIG. 376.—Surgical anatomy of the femoral artery.

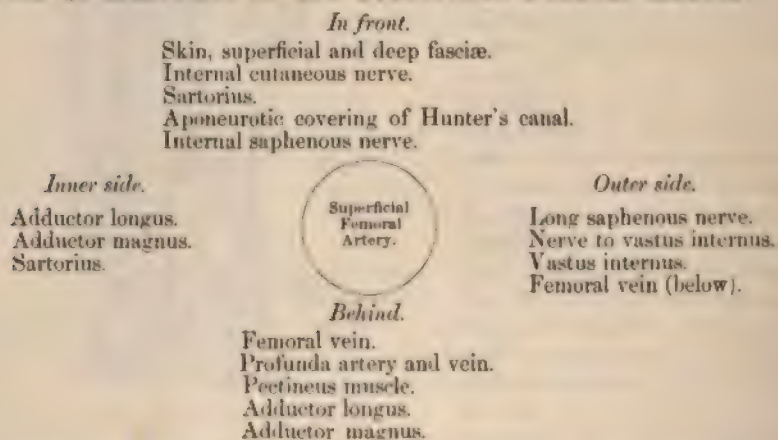

artery and vein are separated, however, from one another by a thin fibrous partition.

PLAN OF RELATIONS OF THE COMMON FEMORAL ARTERY.

The **superficial femoral artery** is only superficial where it lies in Scarpa's triangle. Here it is covered by the skin, superficial and deep fascia, and crossed by the internal cutaneous branch of the anterior crural nerve. In Hunter's canal it is more deeply seated, being covered by the integument, the superficial and deep fascia, the Sartorius and aponeurotic covering of Hunter's canal. The internal saphenous nerve crosses the artery from without inward. Behind, the artery lies at its upper part on the femoral vein and the profunda artery and vein, which separate it from the Pectineus muscle, and lower down on the Adductor longus and Adductor magnus muscles. To the outer side is the long saphenous nerve and the nerve to the Vastus internus, the Vastus internus muscle, and, at its lower part, the femoral vein. To the inner side is the Adductor longus above and the Adductor magnus and Sartorius below.

PLAN OF RELATIONS OF THE SUPERFICIAL FEMORAL ARTERY.

The *femoral vein*, at Poupart's ligament, lies close to the inner side of the artery, separated from it by a thin fibrous partition; but lower down it is behind it, and then to its outer side.

The *internal saphenous nerve* is situated on the outer side of the artery, in the

middle third of the thigh, beneath the aponeurotic covering of Hunter's canal, but not usually within the sheath of the vessels. The internal cutaneous nerve passes obliquely across the upper part of the sheath of the femoral artery.

Peculiarities.—Double Femoral reunited.—Several cases are recorded in which the femoral artery divided into two trunks below the origin of the profunda, and became reunited near the opening in the Adductor magnus so as to form a single popliteal artery. One of them occurred in a patient operated upon for popliteal aneurism.

Change of Position.—A few cases have been recorded in which the femoral artery was situated at the back of the thigh, the vessel being continuous above with the internal iliac, escaping from the pelvis through the great sacro-sciatic foramen, and accompanying the great sciatic nerve to the popliteal space, where its division occurred in the usual manner. The external iliac in these cases was small, and terminated in the profunda.

Position of the Vein.—The femoral vein is occasionally placed along the inner side of the artery, throughout the entire extent of Scarpa's triangle, or it may be slit so that a large vein is placed on each side of the artery for a greater or less extent.

Origin of the Profunda.—This vessel occasionally arises from the inner side, and, more rarely, from the back of the common trunk; but the more important peculiarity, in a surgical point of view, is that which relates to the height at which the vessel arises from the femoral. In three-fourths of a large number of cases it arose between one or two inches below Poupart's ligament; in a few cases the distance was less than an inch; more rarely, opposite the ligament; and in one case, above Poupart's ligament, from the external iliac. Occasionally, the distance between the origin of the vessel and Poupart's ligament exceeds two inches, and in one case it was found to be as much as four inches.

Surface Marking.—The upper two-thirds of a line drawn from a point midway between the anterior superior spine of the ilium and the symphysis pubis to the prominent tuberosity on the inner condyle of the femur, with the thigh abducted and rotated outward, will indicate the course of the femoral artery.

Surgical Anatomy.—*Compression* of the femoral artery, which is constantly requisite in amputations and other operations on the lower limb, and also for the cure of popliteal aneurisms, is most effectually made immediately below Poupart's ligament. In this situation the artery is very superficial, and is merely separated from the horizontal ramus of the os pubis by the Psoas muscle; so that the surgeon, by means of his thumb or a compressor, may effectually control the circulation through it. This vessel may also be compressed in the middle third of the thigh by placing a compress over the artery, beneath the tourniquet, and directing the pressure from within outward, so as to compress the vessel against the inner side of the shaft of the femur.

The **application of a ligature** to the femoral artery may be required in the cases of wound or aneurism of the arteries of the leg, of the popliteal or femoral;¹ and the vessel may be exposed and tied in any part of its course. The great depth of this vessel at its lower part, its close connection with important structures, and the density of its sheath render the operation in this situation one of much greater difficulty than the application of a ligature at its upper part, where it is more superficial.

Ligature of the common femoral artery is usually considered unsafe, on account of the connection of large branches with it—viz. the deep epigastric and the deep circumflex iliac arising just above Poupart's ligament; on account of the number of small branches which arise from it in its short course; and on account of the uncertainty of the origin of the profunda femoris, which, if it arise high up, would be too close to the ligature for the formation of a firm coagulum. The profunda sometimes arises higher than the point above mentioned, and rarely between two or three inches (in one case four) below Poupart's ligament. It would appear, then, that the most favorable situation for the application of a ligature to the femoral is between four and five inches from its point of origin. In order to expose the artery in this situation, an incision between two and three inches long should be made in the course of the vessel, the patient lying in the recumbent position, with the limb slightly flexed and abducted. A large vein is frequently met with, passing in the course of the artery to join the saphena; this must be avoided, and, the fascia lata having been cautiously divided and the Sartorius exposed, that muscle must be drawn outward in order to fully expose the sheath of the vessels. The finger being introduced into the wound and the pulsation of the artery felt, the sheath should be opened on the outer side of the vessel to a sufficient extent to allow of the introduction of the ligature, but no farther; otherwise the nutrition of the coats of the vessel may be interfered with, or muscular branches which arise from the vessel at irregular intervals may be divided. In this part of the operation the long saphenous nerve and the nerve to the Vastus internus, which is in close relation with the sheath, should be avoided. The aneurism needle must be carefully introduced and kept close to the artery, to avoid the femoral vein, which lies behind the vessel in this part of its course.

To expose the artery, in Hunter's canal, an incision should be made through the integument, between three and four inches in length, a finger's breadth internal to the line of the artery, in the middle of the thigh—*i. e.* midway between the groin and the knee. The fascia lata having been divided and the Sartorius muscle exposed, it should be drawn inward, when the strong

¹ Ligature of the femoral artery has been also recommended and performed for elephantiasis of the leg and acute inflammation of the knee-joint (Maunder, *Clin. Soc. Trans.*, vol. ii. p. 37).

fascia which is stretched across from the Adductors to the Vastus internus will be exposed, and must be freely divided; the sheath of the vessels is now seen, and must be opened, and the artery secured by passing the aneurism needle between the vein and artery in the direction from without inward. The femoral vein in this situation lies on the outer side of the artery, the long saphenous nerve on its anterior and outer side.

It has been seen that the femoral artery occasionally divides into two trunks below the origin of the profunda. If in the operation for tying the femoral two vessels are met with, the surgeon should alternately compress each, in order to ascertain which vessel is connected with the aneurismal tumor or with the bleeding from the wound, and that one only should be tied which controls the pulsation or hæmorrhage. If, however, it is necessary to compress both vessels before the circulation in the tumor is controlled, both should be tied, as it would be probable that they became reunited, as in the instances referred to above.

In wounds of the femoral artery the question of the mode of treatment is of considerable importance. If the wound in the superficial structures is a large one, the injured vessel must be exposed and tied; but if the wound is a punctured one and the bleeding has ceased, the question will arise whether to cut down upon the artery or to trust to pressure. Mr. Cripps¹ advises that if the wound is in the "upper part of the thigh—that is to say, in a position where the femoral artery is comparatively superficial—the surgeon may enlarge the opening with a good prospect of finding the wounded vessel without an extensive or prolonged operation. If the wound be in the lower half of the thigh, owing to the greater depth of the artery and the possibility of its being the popliteal that is wounded, the search is rendered a far more severe and hazardous operation, and it should not be undertaken until a thorough trial of pressure has proved ineffectual."

Great care and attention are necessary for the successful application of pressure. The limb should be carefully bandaged from the foot upward to the wound, which is not covered, and then onward to the groin. The wound is then dusted with iodoform or boracic powder and a conical pad applied over the wound. Rollers the thickness of the index finger are then placed along the course of the vessel above and below the wound, and the whole carefully bandaged to a buck splint with a foot-piece.

Collateral Circulation.—When the common femoral is tied the main channels for carrying on the circulation are the anastomoses of the gluteal and circumflex iliac arteries above with the external circumflex below; of the obturator and sciatic above with the internal circumflex below; and of the comes nervi ischiadici with the arteries in the ham.

The principal agents in carrying on the collateral circulation after ligature of the superficial femoral artery are, according to Sir A. Cooper, as follows:

"The arteria profunda formed the new channel for the blood." "The first artery sent off passed down close to the back of the thigh-bone, and entered the two superior articular branches of the popliteal artery."

"The second new large vessel, arising from the profunda at the same part with the former, passed down by the inner side of the Biceps muscle to a branch of the popliteal which was distributed to the Gastrocnemius muscle; whilst a third artery, dividing into several branches, passed down with the sciatic nerve behind the knee-joint, and some of its branches united themselves with the inferior articular arteries of the popliteal, with some recurrent branches of those arteries, with arteries passing to the Gastrocnemii, and, lastly, with the origin of the anterior and posterior tibial arteries."

"It appears, then, that it is those branches of the profunda which accompany the sciatic nerve that are the principal supporters of the new circulation."

In Porta's work² (tab. xii., xiii.) is a good representation of the collateral circulation after the ligature of the femoral artery. The patient had survived the operation three years. The lower part of the artery is at least as large as the upper; about two inches of the vessel appear to have been obliterated. The external and internal circumflex arteries are seen anastomosing by a great number of branches with the lower branches of the femoral (muscular and anastomotica magna) and with the articular branches of the popliteal. The branches from the external circumflex are extremely large and numerous. One very distinct anastomosis can be traced between this artery on the outside and the anastomotica magna on the inside through the intervention of the superior external articular artery, with which they both anastomose; and blood reaches even the anterior tibial recurrent from the external circumflex by means of anastomosis with the same external articular artery. The perforating branches of the profunda are also seen bringing blood round the obliterated portion of the artery into long branches (muscular) which have been given off just below that portion. The termination of the profunda itself anastomoses most freely with the superior external articular. A long branch of anastomosis is also traced down from the internal iliac by means of the comes nervi ischiadici of the sciatic, which anastomoses on the popliteal nerves with branches from the popliteal and posterior tibial arteries. In this case the anastomosis had been too free, since the pulsation and growth of the aneurism recurred, and the patient died after ligature of the external iliac.

There is an interesting preparation in the Museum of the Royal College of Surgeons of a limb on which John Hunter had tied the femoral artery fifty years before the patient's death. The whole of the superficial femoral and popliteal artery seems to have been obliterated. The

¹ Heath's *Dictionary of Practical Surgery*, vol. i. p. 525.

² *Med.-Chir. Trans.*, vol. ii. 1811.

³ *Alterazioni patologiche delle Arterie.*

anastomosis by means of the comes nervi ischiadici, which is shown in Porta's plate, is distinctly seen: the external circumflex and the termination of the profunda artery, seem to have been the chief channels of anastomosis; but the injection has not been a very successful one.

Branches.—The branches of the femoral artery are—the

Superficial Epigastric.	Profunda	External Circumflex.
Superficial Circumflex Iliac.		Internal Circumflex.
Superficial External Pudic.		Three Perforating.
Deep External Pudic.	Muscular.	
Anastomotica Magna.		

The **superficial epigastric** arises from the femoral about half an inch below Poupart's ligament, and, passing through the saphenous opening in the fascia lata, ascends on the abdomen, in the superficial fascia covering the External oblique muscle, nearly as high as the umbilicus. It distributes branches to the superficial inguinal glands, the superficial fascia, and the integument, anastomosing with branches of the deep epigastric.

The **superficial circumflex iliac**, the smallest of the cutaneous branches, arises close to the preceding, and, piercing the fascia lata, runs outward, parallel with Poupart's ligament, as far as the crest of the ilium, dividing into branches which supply the integument of the groin, the superficial fascia, and the superficial inguinal lymphatic glands, anastomosing with the circumflex iliac and with the gluteal and external circumflex arteries.

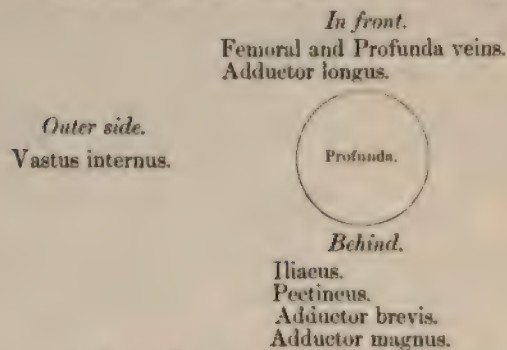

The **superficial external pudic** (superior) arises from the inner side of the femoral artery, close to the preceding vessels, and, after passing through the saphenous opening, courses inward, across the spermatic cord or round ligament, to be distributed to the integument on the lower part of the abdomen, the penis and scrotum in the male, and the labium in the female, anastomosing with branches of the internal pudic.

The **deep external pudic** (inferior), more deeply seated than the preceding, passes inward on the Pectineus muscle, covered by the fascia lata, which it pierces at the inner border of the thigh, its branches being distributed, in the male, to the integument of the scrotum and perineum; and in the female, to the labium, anastomosing with branches of the superficial perineal artery.

The **Profunda Femoris** (*deep femoral artery*) nearly equals the size of the superficial femoral. It arises from the outer and back part of the femoral artery, from one to two inches below Poupart's ligament. It at first lies on the outer side of the superficial femoral, and then passes behind it and the femoral vein to the inner side of the femur, and, passing downward beneath the Adductor longus, terminates at the lower third of the thigh in a small branch which pierces the Adductor magnus (and from this circumstance is sometimes called the fourth perforating artery), and is distributed to the flexor muscles on the back of the thigh, anastomosing with branches of the popliteal and inferior perforating arteries.

Relations.—*Behind*, it lies first upon the Iliacus, and then on the Pectineus, Adductor brevis, and Adductor magnus muscles. *In front*, it is separated from the femoral artery, above by the femoral and profunda veins, and below by the Adductor longus. On its *outer side* the origin of the Vastus internus separates it from the femur.

PLAN OF THE RELATIONS OF THE PROFUNDA ARTERY.

The **External Circumflex Artery** supplies the muscles on the front of the thigh. It arises from the outer side of the profunda, passes horizontally outward, between the divisions of the anterior crural nerve and behind the Sartorius and Rectus muscles, and divides into three sets of branches—ascending, transverse, and descending.

The **ascending branches** pass upward, beneath the Tensor vaginae femoris muscle, to the outer side of the hip, anastomosing with the terminal branches of the gluteal and circumflex iliac arteries.

The **descending branches**, three or four in number, pass downward, behind the Rectus, upon the Vasti muscles, to which they are distributed, one or two passing beneath the Vastus externus as far as the knee, anastomosing with the superior articular branches of the popliteal artery. These are accompanied by the branch of the anterior crural nerve to the Vastus externus.

The **transverse branches**, the smallest and least numerous, pass outward over the Crureus, pierce the Vastus externus, and wind round the femur to its back part, just below the great trochanter, anastomosing at the back of the thigh with the internal circumflex, sciatic, and superior perforating arteries.

The **Internal Circumflex Artery**, smaller than the external, arises from the inner and back part of the profunda, and winds round the inner side of the femur, between the Pectineus and Psoas muscles. On reaching the upper border of the Adductor brevis it gives off two branches, one of which passes inward to be distributed to the Adductor muscles, the Gracilis, and Obturator externus, anastomosing with the obturator artery; the other descends, and passes beneath the Adductor brevis, to supply it and the great Adductor; while the continuation of the vessel passes backward, between the Quadratus femoris and upper border of the Adductor magnus, anastomosing with the sciatic, external circumflex, and superior perforating arteries ("the *crucial anastomosis*"). Opposite the hip-joint this branch gives off an articular vessel, which enters the joint beneath the transverse ligament, and, after supplying the adipose tissue, passes along the round ligament to the head of the bone.

The **Perforating Arteries** (Fig. 375), usually three in number, are so called from their perforating the tendon of the Adductor magnus muscle to reach the back of the thigh. The first is given off above the Adductor brevis, the second in front of that muscle, and the third immediately below it.

The **first or superior perforating artery** passes backward between the Pectineus and Adductor brevis (sometimes perforates the latter); it then pierces the Adductor magnus close to the linea aspera, and divides into branches which supply the Adductor brevis, the Adductor magnus, the Biceps, and Gluteus maximus muscles, anastomosing with the sciatic, internal and external circumflex, and middle perforating arteries.

The **second or middle perforating artery**, larger than the first, pierces the tendons of the Adductor brevis and Adductor magnus muscles, and divides into ascending and descending branches, which supply the flexor muscles of the thigh.

anastomosing with the superior and inferior perforating. The nutrient artery of the femur is usually given off from this branch.

The **third or inferior perforating artery** is given off below the Adductor brevis; it pierces the Adductor magnus, and divides into branches which supply the flexor muscles of the thigh, anastomosing above with the perforating arteries, and below with the terminal branches of the profunda and the muscular branches of the popliteal.

Muscular branches are given off from the superficial femoral throughout its entire course. They vary from two to seven in number, and supply chiefly the Sartorius and Vastus internus.

The **Anastomotica Magna** arises from the femoral artery just before it passes through the tendinous opening in the Adductor magnus muscle, and divides into a superficial and deep branch.

The **superficial branch** accompanies the long saphenous nerve beneath the Sartorius, and, piercing the fascia lata, is distributed to the integument.

The **deep branch** descends in the substance of the Vastus internus, lying in front of the tendon of the Adductor magnus, to the inner side of the knee, where it anastomoses with the superior internal articular artery and anterior recurrent branch of the anterior tibial. A branch from this vessel crosses outward above the articular surface of the femur, forming an anastomotic arch with the superior external articular artery, and supplies branches to the knee-joint.

Popliteal Artery.

The **popliteal artery** commences at the termination of the femoral at the opening in the Adductor magnus, and, passing obliquely downward and outward behind the knee-joint to the lower border of the Popliteus muscle, divides into the *anterior* and *posterior tibial arteries*. A portion of the artery lies in the popliteal space; but above, to a slight extent, and below, to a considerable extent, it is covered by the muscles which form the boundaries of the space, and is therefore beyond the confines of the hollow.

THE POPLITEAL SPACE (Fig. 377).

Dissection.—A vertical incision about eight inches in length should be made along the back part of the knee-joint, connected above and below by a transverse incision from the inner to the outer side of the limb. The flaps of integument included between these incisions should be reflected in the direction shown in Fig. 328, page 516.

Boundaries.—The **popliteal space**, or the **ham**, is a lozenge-shaped space, widest at the back part of the knee-joint and deepest above the articular end of the femur. It is bounded externally, above the joint, by the Biceps, and, below the joint, by the Plantaris and external head of the Gastrocnemius; internally, above the joint, by the Semimembranosus, Semitendinosus, Gracilis, and Sartorius; below the joint, by the inner head of the Gastrocnemius.

Above, it is limited by the apposition of the inner and outer hamstring muscles; below, by the junction of the two heads of the Gastrocnemius. The floor is formed by the lower part of the posterior surface of the shaft of the femur, the posterior ligament of the knee-joint, the upper end of the tibia, and the fascia covering the Popliteus muscle, and the space is covered in by the fascia lata.

Contents.—It contains the popliteal vessels and their branches, together with the termination of the external saphenous vein, the internal and external popliteal nerves and some of their branches, the lower extremity of the small sciatic nerve, the articular branch from the obturator nerve, a few small lymphatic glands, and a considerable quantity of loose adipose tissue.

Position of Contained Parts.—The internal popliteal nerve descends in the middle line of the space, lying superficial and crossing the artery from without inward. The external popliteal nerve descends on the outer side of the space,

lying close to the tendon of the Biceps muscle. More deeply at the bottom of the space are the popliteal vessels, the vein lying superficial and a little external to the artery, to which it is closely united by dense areolar tissue; sometimes the vein is placed on the inner instead of the outer side of the artery; or the vein may be double, the artery lying between the two venæ comites, which are usually connected by short transverse branches. More deeply, and, at its upper part, close to the surface of the bone, is the popliteal artery, and passing off from it at right angles are its articular branches. The articular branch from the obturator nerve descends upon the popliteal artery to supply the knee, and occasionally there is found deep in the space an articular filament from the great sciatic nerve. The popliteal lymphatic glands, four or five in number, are found surrounding the artery: one usually lies superficial to the vessel; another is situated between it and the bone, and the rest are placed on either side of it.

The **Popliteal Artery**, in its course downward from the aperture in the Adductor magnus to the lower border of the Popliteus muscle, rests first on the inner surface of the femur, and is then separated by a little fat from the hollowed popliteal surface of the bone; in the middle of its course it rests on the posterior ligament of the knee-joint, and below on the fascia covering the Popliteus muscle. *Superficially*, it is covered above by the Semimembranosus; in the middle of its course, by a quantity of fat, which separates it from the deep fascia and integument; and below it is overlapped by the Gastrocnemius, Plantaris, and Soleus muscles, the popliteal vein, and the internal popliteal nerve. The popliteal vein, which is intimately attached to the artery, lies superficial and external to it until near the termination of the artery, when the vein crosses it and lies to its inner side. The popliteal nerve is still more superficial and external above, but below the joint it crosses the artery and lies on its inner side. *Laterally*, the artery is bounded by the muscles which are situated on either side of the popliteal space.

PLAN OF RELATIONS OF POPLITEAL ARTERY.

Peculiarities in Point of Division.—Occasionally the popliteal artery divides prematurely into its terminal branches; this unusual division occurs most frequently opposite the knee-joint.

Unusual Branches.—The artery sometimes divides into the anterior tibial and peroneal, the posterior tibial being wanting or very small. Occasionally the popliteal is found to divide into three branches, the anterior and posterior tibial and peroneal.

Surface Marking.—The course of the upper part of the popliteal artery is indicated by a line drawn from the outer border of the Semimembranosus muscle at the junction of the middle and lower third of the thigh obliquely downward to the middle of the popliteal space, exactly behind the knee-joint. From this point it passes vertically downward to the level of a line drawn through the lower part of the tubercle of the tibia.

Surgical Anatomy.—The popliteal artery is not infrequently the seat of injury. It may be torn by direct violence, as by the passage of a cart-wheel over the knee or by hyper-extension of the knee; and in the dead body, at all events, the middle and internal coats may be ruptured by extreme flexion. It may also be lacerated by fracture of the lower part of the shaft of the

femur or by antero-posterior dislocation of the knee-joint. It has been torn in breaking down adhesions in cases of fibrous ankylosis of the knee, and is in danger of being wounded, and in fact has been wounded, in performing Macewen's operation of osteotomy of the lower end of the femur for genu valgum. In addition, Spencer records a case in which the popliteal artery was wounded from in front by a stab just below the knee, the knife passing through the interosseous space. The popliteal artery is more frequently the seat of aneurism than is any other artery in the body, with the exception of the thoracic aorta. This is due no doubt, in a great measure to the amount of movement to which it is subjected, and to the fact that it is supported by loose and lax tissue only, and not by muscles, as is the case with most arteries.

Ligature of the popliteal artery is required in cases of wound of that vessel, but for aneurism of the posterior tibial it is preferable to tie the superficial femoral. The popliteal may be tied in the upper or lower part of its course; but in the middle of the ham the operation is attended with considerable difficulty, from the great depth of the artery and from the extreme degree of tension of the lateral boundaries of the space.

In order to expose the vessel in the upper part of its course the patient should be placed in the prone position, with the limb extended. An incision about three inches in length should then be made through the integument, along the posterior margin of the Semimembranosus, and the fascia lata having been divided, this muscle must be drawn inward. The internal popliteal nerve will be first exposed, lying very superficial and external to the artery; beneath this will be seen the popliteal vein, and, still deeper and to its inner side, the artery. The vein and nerve must be cautiously separated from the artery, and the aneurism needle passed around the vessel from without inward.

To expose the vessel in the lower part of its course, where the artery lies between the two heads of the Gastrocnemius, the patient should be placed in the same position as in the preceding operation. An incision should then be made through the integument in the middle line, commencing opposite the bend of the knee-joint, care being taken to avoid the external saphenous vein and nerve. After dividing the deep fascia and separating some dense cellular membrane, the artery, vein, and nerve will be exposed, descending between the two heads of the Gastrocnemius. Some muscular branches of the popliteal should be avoided if possible, or, if divided, tied immediately. The leg being now flexed, in order the more effectually to separate the two heads of the Gastrocnemius the nerve should be drawn inward and the vein outward, and the aneurism needle passed between the artery and vein from without inward.

In cases where the artery has been wounded during an osteotomy of the lower end of the femur it would be most conveniently secured from the front at the inner side of the thigh. The knee is flexed and the limb placed on its outer side. An incision, three inches long, is made parallel to and immediately behind the tendon of the Adductor magnus from the junction of the middle and lower third of the thigh. Skin, superficial and deep fascia are to be divided, care being taken of the internal saphenous vein; the Adductor magnus is to be drawn forward and the inner hamstring tendons backward, and the artery will be found surrounded by fat. The nerve and vein are usually not seen, as they lie to the outer side of the artery.

The branches of the popliteal artery are—the

Muscular	Superior.	Superior Internal Articular.
	Inferior or Sural.	Azygos Articular.
Cutaneous.		Inferior External Articular.
Superior External Articular.		Inferior Internal Articular.

The **superior muscular branches**, two or three in number, arise from the upper part of the popliteal artery, and are distributed to the Vastus externus and flexor muscles of the thigh, anastomosing with the inferior perforating and terminal branches of the profunda.

The **inferior muscular (sural)** are two large branches which are distributed to the two heads of the Gastrocnemius and to the Plantaris muscle. They arise from the popliteal artery opposite the knee-joint.

Cutaneous branches descend on each side and in the middle of the limb, between the Gastrocnemius and integument; they arise separately from the popliteal artery or from some of its branches, and supply the integument of the calf.

The **superior articular arteries**, two in number, arise one on each side of the popliteal, and wind round the femur immediately above its condyles to the front of the knee-joint. The *internal branch* passes beneath the tendon of the Adductor magnus, and divides into two, one of which supplies the Vastus internus, inosculating with the anastomotica magna and inferior internal articular; the other ramifies close to the surface of the femur, supplying it and the knee-joint, and anastomosing with the superior external articular artery. The *external branch* passes above the outer condyle, beneath the tendon of the Biceps, and divides into

of the femur and knee-joint, and forms an anastomotic arch across the bone with the *anastomotica magna* and the inferior internal articular arteries.

The *azygos articular* is a small branch arising from the popliteal artery opposite the bend of the knee-joint. It pierces the posterior ligament, and supplies the ligaments and synovial membrane in the interior of the articulation.

The *inferior articular arteries*, two in number, arise from the popliteal beneath the Gastrocnemius, and wind round the head of the tibia below the joint. The *internal* one passes below the inner tuberosity, beneath the internal lateral ligament, at the anterior border of which it ascends to the front and inner side of the joint, to supply the head of the tibia and the articulation of the knee, anastomosing with the inferior external articular and superior internal articular arteries. The *external* one passes outward above the head of the fibula, to the front of the knee-joint, passing in its course beneath the outer head of the Gastrocnemius, the external lateral ligament, and the tendon of the Biceps muscle, and divides into branches which anastomose with the inferior internal articular artery, the superior external articular artery, and the anterior recurrent branch of the anterior tibial.

Circumpatellar Anastomosis.—Around and above the patella, and on the contiguous ends of the femur and tibia, is a large network of vessels, forming a superficial and deep plexus from which numerous offsets proceed into the interior of the joint. The arteries from which this plexus is formed are the two internal and two external articular branches of the popliteal, the *anastomotica magna*, the terminal branch of the profunda, the descending branch from the external circumflex, and the anterior recurrent branch of the anterior tibial.

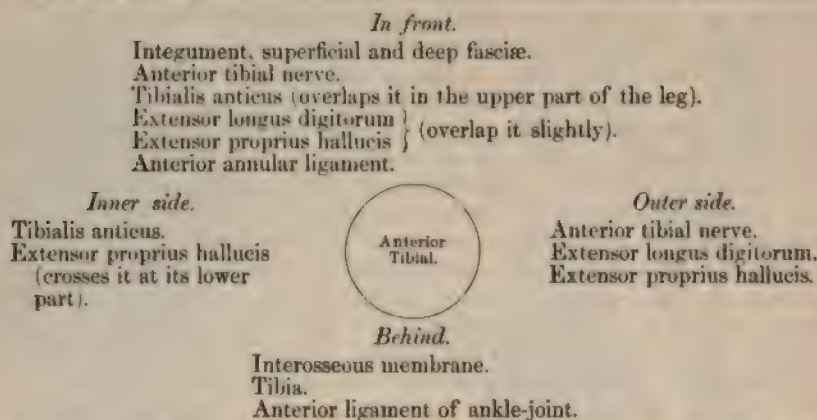

The Anterior Tibial Artery (Fig. 378).

The *anterior tibial artery* commences at the bifurcation of the popliteal at the lower border of the Popliteus muscle, passes forward between the two heads of the Tibialis posticus, and through the large oval aperture above the upper border of the interosseous membrane to the deep part of the front of the leg: it then descends on the anterior surface of the interosseous membrane, gradually approaching the tibia; and at the lower part of the leg lies on this bone, and then on the anterior ligament of the ankle to the bend of the ankle-joint, where it lies more superficially, and becomes the *dorsalis pedis*.

Relations.—In the upper two-thirds of its extent it rests upon the interosseous membrane, to which it is connected by delicate fibrous arches thrown across it; in the lower third, upon the front of the tibia and the anterior ligament of the ankle-joint. In the upper third of its course it lies between the Tibialis anticus and Extensor longus digitorum; in the middle third, between the Tibialis anticus and Extensor proprius hallucis. At the bend of the ankle it is crossed by the tendon of the Extensor proprius hallucis, and lies between it and the innermost tendon of the Extensor longus digitorum. It is covered, in the upper two-thirds of its course, by the muscles which lie on either side of it and by the deep fascia; in the lower third, by the integument, anterior annular ligament, and fascia.

The anterior tibial artery is accompanied by two veins (*venæ comites*), which lie one on each side of the artery; the anterior tibial nerve lies at first to its outer side, and about the middle of the leg is placed superficial to it; at the lower part of the artery the nerve is generally again on the outer side.

PLAN OF THE RELATIONS OF THE ANTERIOR TIBIAL ARTERY.

Peculiarities in Size.—This vessel may be diminished in size, may be deficient to a greater or less extent, or may be entirely wanting, its place being supplied by perforating branches from the posterior tibial or by the anterior division of the peroneal artery.

Course.—The artery occasionally deviates in its course toward the fibular side of the leg, regaining its usual position beneath the annular ligament at the front of the ankle. In two instances the vessel has been found to approach the surface in the middle of the leg, being covered merely by the integument and fascia below that point.

Surface Marking.—A line drawn from the inner side of the head of the fibula to midway between the two malleoli will mark the course of the artery, the point where the artery comes in front of the interosseous membrane being in this line, one and a quarter inches below the level of the head of the fibula.

Surgical Anatomy.—The anterior tibial artery may be tied in the upper or lower part of the leg. In the upper part the operation is attended with great difficulty, on account of the depth of the vessel from the surface. An incision about four inches in length, should be made through the integument, midway between the spine of the tibia and the outer margin of the fibula, the fascia and intermuscular septum between the Tibialis anticus and Extensor longus digitorum being divided to the same extent. The foot must be flexed to relax these muscles, and they must be separated from each other by the finger. The artery is then exposed deeply seated, lying upon the interosseous membrane, the nerve lying externally, and one of the venæ comites on either side; these must be separated from the artery before the aneurism needle is passed round it.

To tie the vessel in the lower third of the leg above the ankle-joint an incision about three inches in length should be made through the integument between the tendons of the Tibialis anticus and Extensor proprius hallucis muscles, the deep fascia being divided to the same extent. The tendon on either side should be held aside, when the vessel will be seen lying upon the tibia, with the nerve superficial to it and one of the venæ comites on either side.

The branches of the anterior tibial artery are—the

Posterior Recurrent Tibial.	Muscular.
Superior Fibular.	Internal Malleolar.
Anterior Recurrent Tibial.	External Malleolar.

The **posterior recurrent tibial** is not a constant branch, and is given off from the anterior tibial before that vessel passes through the interosseous space. It ascends beneath the Popliteus muscle, which it supplies, and anastomoses with the lower articular branches of the popliteal artery, giving off an offset to the superior tibio-fibular joint.

The **superior fibular** is sometimes given off from the anterior tibial, sometimes from the posterior tibial. It passes outward, round the neck of the fibula, through the Soleus, which it supplies, and ends in the substance of the Peroneus longus muscle.

The **anterior recurrent tibial branch** arises from the anterior tibial as soon as that vessel has passed through the interosseous space; it ascends in the Tibialis anticus muscle, and ramifies on the front and sides of the knee-joint, anastomosing with the articular branches of the popliteal and with the anastomotica magna.

The **muscular branches** are numerous: they are distributed to the muscles

which lie on each side of the vessel, some piercing the deep fascia to supply the integument, others passing through the interosseous membrane, and anastomosing with branches of the posterior tibial and peroneal arteries.

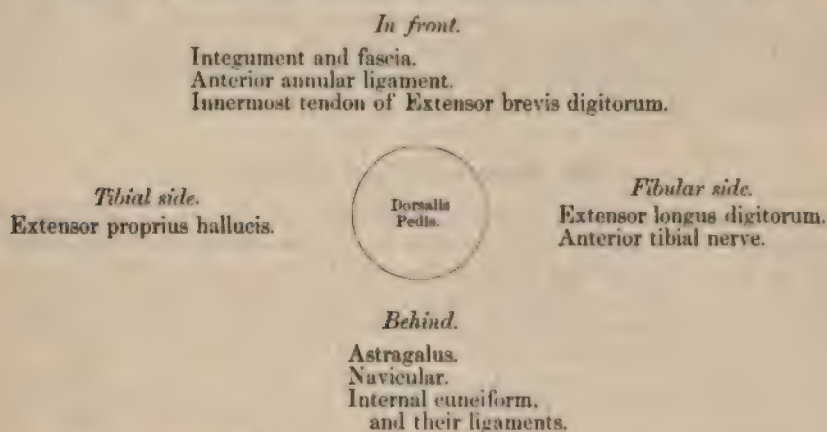

The **malleolar arteries** supply the ankle-joint. The *internal* arises about two inches above the articulation, and passes beneath the tendons of the Extensor proprius hallucis and Tibialis anticus to the inner ankle, upon which it ramifies, anastomosing with branches of the posterior tibial and internal plantar arteries and with the internal calcanean from the posterior tibial. The *external* passes beneath the tendons of the Extensor longus digitorum and Peroneus tertius, and supplies the outer ankle, anastomosing with the anterior peroneal artery and with ascending branches from the tarsal branch of the dorsalis pedis.

The Dorsalis Pedis Artery (Fig. 378).

The **dorsalis pedis**, the continuation of the anterior tibial, passes forward from the bend of the ankle along the tibial side of the foot to the back part of the first intermetatarsal space, where it divides into two branches, the *dorsalis hallucis* and *communicating*.

Relations.—This vessel, in its course forward, rests upon the astragalus, navicular, and internal cuneiform bones and the ligaments connecting them, being covered by the integument and fascia, anterior annular ligament, and crossed near its termination by the innermost tendon of the Extensor brevis digitorum. On its *tibial side* is the tendon of the Extensor proprius hallucis; on its *fibular side*, the innermost tendon of the Extensor longus digitorum, and the termination of the anterior tibial nerve. It is accompanied by two veins.

PLAN OF THE RELATIONS OF THE DORSALIS PEDIS ARTERY.

Peculiarities in Size.—The dorsal artery of the foot may be larger than usual, to compensate for a deficient plantar artery; or it may be deficient in its terminal branches to the toes, which are then derived from the internal plantar; or its place may be supplied altogether by a large anterior peroneal artery.

Position.—This artery frequently curves outward, lying external to the line between the middle of the ankle and the back part of the first interosseous space.

Surface Marking.—The dorsalis pedis artery is indicated on the surface of the dorsum of the foot by a line drawn from the centre of the space between the two malleoli to the back of the first intermetatarsal space.

Surgical Anatomy.—This artery may be tied, by making an incision through the integument between two and three inches in length, on the fibular side of the tendon of the Extensor proprius hallucis, in the interval between it and the inner border of the short Extensor muscle. The incision should not extend farther forward than the back part of the first intermetatarsal space, as the artery divides in that situation. The deep fascia being divided to the same extent, the artery will be exposed, the nerve lying upon its outer side.

Branches.—The branches of the *dorsalis pedis* are—the

Tarsal.	Dorsalis Hallucis.
Metatarsal—Interosseous.	Communicating.

The **tarsal artery** arises from the *dorsalis pedis*, as that vessel crosses the navicular bone; it passes in an arched direction outward, lying upon the tarsal bones, and covered by the *Extensor brevis digitorum*; it supplies that muscle and the articulations of the tarsus, and anastomoses with branches from the metatarsal, external malleolar, peroneal, and external plantar arteries.

The **metatarsal** arises a little anterior to the preceding; it passes outward to the outer part of the foot, over the bases of the metatarsal bones, beneath the tendons of the short *Extensor*, its direction being influenced by its point of origin; and it anastomoses with the tarsal and external plantar arteries. This vessel gives off three branches, the *interosseous arteries*, which pass forward upon the three outer *Dorsal interossei* muscles, and, in the clefts between the toes, divide into two dorsal collateral branches for the adjoining toes. At the back part of each interosseous space these vessels receive the posterior perforating branches from the plantar arch, and at the fore part of each interosseous space they are joined by the anterior perforating branches from the digital arteries. The outermost interosseous artery gives off a branch which supplies the outer side of the little toe.

The **dorsalis hallucis** runs forward along the outer border of the first metatarsal bone, and at the cleft between the first and second toes divides into two branches, one of which passes inward, beneath the tendon of the *Extensor proprius hallucis*, and is distributed to the inner border of the great toe; the outer branch bifurcates, to supply the adjoining sides of the great and second toes.

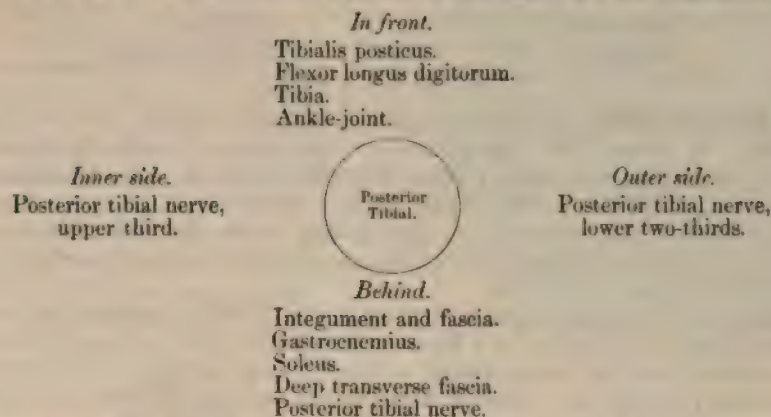

The **communicating artery** dips down into the sole of the foot, between the two heads of the *First dorsal interosseous* muscle, and inosculates with the termination of the external plantar artery to complete the plantar arch. It here gives off two digital branches: one runs along the inner side of the great toe on its plantar surface; the other passes forward along the first interosseous space, and bifurcates for the supply of the adjacent sides of the great and second toes.

The Posterior Tibial Artery.

The **posterior tibial** is an artery of large size, which extends obliquely downward from the lower border of the *Popliteus* muscle, along the tibial side of the leg, to the fossa between the inner ankle and the heel, where it divides beneath the origin of the *Abductor hallucis*, on a level with a line drawn from the point of the internal malleolus to the centre of the convexity of the heel, into the *internal* and *external plantar arteries*. At its origin it lies opposite the interval between the tibia and fibula; as it descends, it approaches the inner side of the leg, lying behind the tibia, and, in the lower part of its course, is situated midway between the inner malleolus and the tuberosity of the *os calcis*.

Relations.—It lies successively upon the *Tibialis posticus*, the *Flexor longus digitorum*, the tibia, and the back part of the ankle-joint. It is covered by the deep transverse fascia, which separates it above from the *Gastrocnemius* and *Soleus* muscles. In the lower third, where it is more superficial, it is covered only by the integument and fascia, and runs parallel with the inner border of the *tendo Achillis*. It is accompanied by two veins, and by the posterior tibial nerve, which lies at first to the inner side of the artery, but soon crosses it, and is, in the greater part of its course, on its outer side.

PLAN OF THE RELATIONS OF THE POSTERIOR TIBIAL ARTERY.

Behind the Inner ankle the tendons and blood-vessels are arranged in the following order, from within outward: First, the tendons of the Tibialis posticus and Flexor longus digitorum, lying in the same groove, behind the inner malleolus, the former being the most internal. External to these is the posterior tibial artery, having a vein on either side; and, still more externally, the posterior tibial nerve. About half an inch nearer the heel is the tendon of the Flexor longus hallucis.

Peculiarities in Size.—The posterior tibial is not unfrequently smaller than usual, or absent, its place being supplied by a large peroneal artery which passes inward at the lower end of the tibia, and either joins the small tibial artery or continues alone to the sole of the foot.

Surface Marking.—The course of the posterior tibial artery is indicated by a line drawn from a point one inch below the centre of the popliteal space to midway between the tip of the internal malleolus and the centre of the convexity of the heel.

Surgical Anatomy.—The application of a ligature to the posterior tibial may be required in cases of wound of the sole of the foot attended with great hæmorrhage, when the vessel should be tied at the inner ankle. In cases of wound of the posterior tibial it will be necessary to enlarge the opening so as to expose the vessel at the wounded point, excepting where the vessel is injured by a punctured wound from the front of the leg. In cases of aneurism from wound of the artery low down, the vessel should be tied in the middle of the leg. But in aneurism of the posterior tibial high up it would be better to tie the femoral artery.

To tie the posterior tibial artery at the ankle, a semilunar incision should be made through the integument, about two inches and a half in length, midway between the heel and inner ankle or a little nearer the latter. The subcutaneous cellular tissue having been divided, a strong and dense fascia, the internal annular ligament, is exposed. This ligament is continuous above with the deep fascia of the leg, covers the vessels and nerves, and is intimately adherent to the sheaths of the tendons. This having been cautiously divided upon a director, the sheath of the vessels is exposed, and, being opened, the artery is seen with one of the venæ comites on each side. The aneurism needle should be passed round the vessel from the heel toward the ankle, in order to avoid the posterior tibial nerve, care being at the same time taken not to include the venæ comites.

The vessel may also be tied in the lower third of the leg by making an incision, about three inches in length, parallel with the inner margin of the tendo Achillis. The internal saphenous vein being carefully avoided, the two layers of fascia must be divided upon a director, when the artery is exposed along the outer margin of the Flexor longus digitorum, with one of its venæ comites on either side and the nerve lying external to it.

To tie the posterior tibial in the middle of the leg is a very difficult operation, on account of the great depth of the vessel from the surface. The patient being placed in the recumbent position, the injured limb should rest on its outer side, the knee being partially bent and the foot extended, so as to relax the muscles of the calf. An incision about four inches in length should then be made through the integument a finger's breadth behind the inner margin of the tibia, taking care to avoid the internal saphenous vein. The deep fascia having been divided, the margin of the Gastrocnemius is exposed, and must be drawn aside, and the tibial attachment of the Soleus divided, a director being previously passed beneath it. The artery may now be felt pulsating beneath the deep fascia about an inch from the margin of the tibia. The fascia having been divided, and the limb placed in such a position as to relax the muscles of the calf as much as possible, the veins should be separated from the artery, and the aneurism needle passed round the vessel from without inward, so as to avoid wounding the posterior tibial nerve.

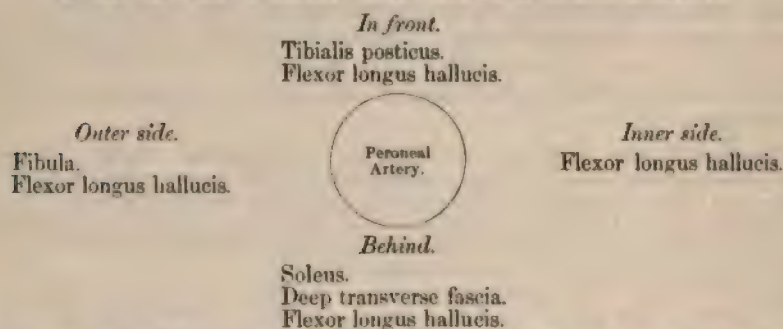

The branches of the posterior tibial artery are—the

Peroneal.	Nutrient.
Muscular.	Communicating.
Internal Calcanean.	

The **Peroneal Artery** lies, deeply seated, along the back part of the fibular side of the leg. It arises from the posterior tibial about an inch below the lower border of the Popliteus muscle, passes obliquely outward to the fibula, and then descends along the inner border of that bone to the lower third of the leg, where it gives off the *anterior peroneal*. It then passes across the articulation between the tibia and fibula to the outer side of the os calcis, where it gives off its terminal branches, the *external calcanean*.

Relations.—This vessel rests at first upon the Tibialis posticus, and then, for the greater part of its course, in a fibrous canal between the origins of the Flexor longus hallucis and Tibialis posticus, covered or surrounded by the fibres of the Flexor longus hallucis. It is *covered*, in the upper part of its course, by the Soleus and deep transverse fascia; *below*, by the Flexor longus hallucis.

PLAN OF THE RELATIONS OF THE PERONEAL ARTERY.

Peculiarities in Origin.—The peroneal artery may arise three inches below the Popliteus, or from the posterior tibial high up, or even from the popliteal.

Its size is more frequently increased than diminished; and then it either reinforces the posterior tibial by its junction with it, or altogether takes the place of the posterior tibial in the lower part of the leg and foot, the latter vessel only existing as a short muscular branch. In those rare cases where the peroneal artery is smaller than usual a branch from the posterior tibial supplies its place, and a branch from the anterior tibial compensates for the diminished anterior peroneal artery. In one case the peroneal artery has been found entirely wanting.

The anterior peroneal is sometimes enlarged, and takes the place of the dorsal artery of the foot.

The branches of the peroneal are—the

Muscular.	Communicating.
Nutrient.	Posterior Peroneal.
Anterior Peroneal.	External Calcanean.

Muscular Branches.—The peroneal artery, in its course, gives off branches to the Soleus, Tibialis posticus, Flexor longus hallucis, and Peronei muscles.

The **nutrient artery** supplies the fibula.

The **Anterior peroneal** pierces the interosseous membrane, about two inches above the outer malleolus, to reach the fore part of the leg, and, passing down beneath the Peroneus tertius to the outer ankle, ramifies on the front and outer side of the tarsus, anastomosing with the external malleolar and tarsal arteries.

The **communicating** is given off from the peroneal about an inch from its lower end, and, passing inward, joins the communicating branch of the posterior tibial.

The **Posterior peroneal** passes down behind the outer ankle to the back of the external malleolus, to terminate in branches which ramify on the outer surface and back of the os calcis.

The **External calcanean** are the terminal branches of the peroneal artery; they pass to the outer side of the heel, and communicate with the external malleolar, and, on the back of the heel, with the internal calcanean arteries.

The **nutrient artery** of the tibia arises from the posterior tibial near its origin, and, after supplying a few muscular branches, enters the nutrient canal of that bone, which it traverses obliquely from above downward. This is the largest nutrient artery of bone in the body.

The **muscular branches** of the posterior tibial are distributed to the Solens and deep muscles along the back of the leg.

The **communicating branch**, to join a similar branch of the peroneal, runs transversely across the back of the tibia, about two inches above its lower end, passing beneath the Flexor longus hallucis.

The **internal calcanean** are several large arteries which arise from the posterior

FIG. 379.—The plantar arteries. Superficial view.

FIG. 380.—The plantar arteries. Deep view.

tibial just before its division: they are distributed to the fat and integument behind the tendo Achillis and about the heel, and to the muscles on the inner side of the sole, anastomosing with the peroneal and internal malleolar, and, on the back of the heel, with the external calcanean arteries.

The **Internal Plantar Artery** (Figs. 379, 380), much smaller than the external, passes forward along the inner side of the foot. It is at first situated above¹ the Abductor hallucis, and then between it and the Flexor brevis digitorum, both of which it supplies. At the base of the first metatarsal bone, where it has become much diminished in size, it passes along the inner border of the great toe, inosculating with its digital branch.

The **External Plantar Artery**, much larger than the internal, passes obliquely outward and forward to the base of the fifth metatarsal bone. It then turns obliquely inward to the interval between the bases of the first and second metatarsal bones, where it anastomoses with the communicating branch from the dorsalis pedis artery, thus completing the *plantar arch*. As this artery passes

¹ This refers to the erect position of the body. In the ordinary position for dissection the artery is deeper than the muscle.

outward, it is first placed between the os calcis and Abductor hallucis, and then between the Flexor brevis digitorum and Flexor accessorius, and as it passes forward to the base of the little toe, it lies more superficially between the Flexor brevis digitorum and Abductor minimi digiti, covered by the deep fascia and integument. The remaining portion of the vessel is deeply situated: it extends from the base of the metatarsal bone of the little toe to the back part of the first interosseous space, and forms the plantar arch; it is convex forward, lies upon the Interossei muscles opposite the tarsal ends of the metatarsal bones, and is covered by the Adductor obliquus hallucis, the flexor tendons of the toes, and the Lumbricales.

Surface Marking.—The course of the internal plantar artery is represented by a line drawn from the mid-point between the tip of the internal malleolus and the centre of the convexity of the heel to the middle of the under surface of the great toe; the external plantar by a line from the same point to within a finger's breadth of the tuberosity of the fifth metatarsal bone. The plantar arch is indicated by a line drawn from this point; *i. e.* a finger's breadth internal to the tuberosity of the fifth metatarsal bone transversely across the foot to the back of the first interosseous space.

Surgical Anatomy.—Wounds of the plantar arch are always serious, on account of the depth of the vessel and the important structures which must be interfered with in an attempt to ligature it. Delorme has shown that it may be ligatured from the dorsum of the foot in almost any part of its course by removing a portion of one of the three middle metatarsal bones.

Branches.—The plantar arch, besides distributing numerous branches to the muscles, integument, and fasciæ in the sole, gives off the following branches:

Posterior Perforating.

Digital—Anterior Perforating.

The **Posterior Perforating** are three small branches which ascend through the back part of the three outer interosseous spaces, between the heads of the Dorsal interossei muscles, and anastomose with the interosseous branches from the metatarsal artery.

The **Digital Branches** are four in number, and supply the three outer toes and half the second toe. The *first* passes outward from the outer side of the plantar arch, and is distributed to the outer side of the little toe, passing in its course beneath the Abductor and short Flexor muscles. The *second*, *third*, and *fourth* run forward along the interosseous spaces, and on arriving at the clefts between the toes divide into collateral branches, which supply the adjacent sides of the three outer toes and the outer side of the second. At the bifurcation of the toes each digital artery sends upward, through the fore part of the corresponding interosseous space, a small branch, which inosculates with the interosseous branches of the metatarsal artery. These are the *anterior perforating branches*.

From the arrangement already described of the distribution of the vessels to the toes it will be seen that both sides of the three outer toes and the outer side of the second toe are supplied by branches from the plantar arch; both sides of the great toe and the inner side of the second are supplied by the communicating branch of the dorsalis pedis.

THE VEINS.

THE Veins are the vessels which serve to return the blood from the capillaries of the different parts of the body to the heart. They consist of two distinct sets of vessels, the *pulmonary* and *systemic*.

The **Pulmonary Veins** are concerned in the circulation in the lungs. Unlike other vessels of this kind, they contain arterial blood, which they return from the lungs to the left auricle of the heart.

The **Systemic Veins** are concerned in the general circulation; they return the venous blood from the body generally to the right auricle of the heart.

The **Portal Vein**, an appendage to the systemic venous system, is confined to the abdominal cavity, returning the venous blood from the viscera of digestion, and carrying it to the liver by a single trunk of large size, the *vena porta*. This vessel ramifies in the substance of the liver and breaks up into a minute network of capillaries. These capillaries then re-collect to form the hepatic veins, by which the blood is conveyed to the inferior vena cava.

The veins, like the arteries, are found in nearly every tissue of the body. They commence by minute plexuses which receive the blood from the capillaries. The branches which have their commencement in these plexuses unite together into trunks, and these, in their passage toward the heart, constantly increase in size as they receive tributaries or join other veins. The veins are larger and altogether more numerous than the arteries; hence the entire capacity of the venous system is much greater than that of the arterial, the pulmonary veins excepted, which do not exceed in capacity the pulmonary arteries. From the combined area of the smaller venous branches being greater than the main trunks, it results that the venous system represents a cone, the summit of which corresponds to the heart, its base to the circumference of the body. In form the veins are not perfectly cylindrical like the arteries, their walls being collapsed when empty, and the uniformity of their surface being interrupted at intervals by slight constrictions, which indicate the existence of valves in their interior. They usually retain, however, the same calibre as long as they receive no branches.

The veins communicate very freely with one another, especially in certain regions of the body, and this communication exists between the larger trunks as well as between the smaller branches. Thus, in the cavity of the cranium and between the veins of the neck, where obstruction would be attended with imminent danger to the cerebral venous system, we find that the sinuses and larger veins have large and very frequent anastomoses. The same free communication exists between the veins throughout the whole extent of the spinal canal, and between the veins composing the various venous plexuses in the abdomen and pelvis, as the spermatic, uterine, vesical, and prostatic.

The systemic veins are subdivided into three sets: superficial, deep, and sinuses.

The **Superficial or Cutaneous Veins** are found between the layers of the superficial fascia, immediately beneath the integument; they return the blood from these structures, and communicate with the deep veins by perforating the deep fascia.

The **Deep Veins** accompany the arteries, and are usually enclosed in the same sheath with those vessels. With the smaller arteries—as the radial, ulnar, brachial, tibial, peroneal—they exist generally in pairs, one lying on each side of the vessel, and are called *venæ comites*. The larger arteries—as the axillary, subclavian, popliteal, and femoral—have usually only one accompanying vein. In certain

organs of the body, however, the deep veins do not accompany the arteries; for instance, the veins in the skull and spinal canal, the hepatic veins in the liver, and the larger veins returning blood from the osseous tissue.

Sinuses are venous channels which, in their structure and mode of distribution, differ altogether from the veins. They are found only in the interior of the skull, and are formed by a separation of the layers of the dura mater, their outer coat consisting of fibrous tissue, their inner of an endothelial layer continuous with the lining membrane of the veins.

Veins have thinner walls than arteries, the difference in thickness being due to the small amount of elastic and muscular tissues which the veins contain. The superficial veins usually have thicker coats than the deep veins, and the veins of the lower limb are thicker than those of the upper.

The minute structure of these vessels has been described in the section on General Anatomy.

THE PULMONARY VEINS.

The *Pulmonary Veins* return the arterial blood from the lungs to the left auricle of the heart. They are four in number, two for each lung. The pulmonary differ from other veins in several respects: 1. They carry arterial instead of venous blood. 2. They are destitute of valves. 3. They are only slightly larger than the arteries they accompany. 4. They accompany those vessels singly. They commence in a capillary network upon the walls of the air-cells, where they are continuous with the ramifications of the pulmonary artery, and, uniting together, form a single trunk for each lobule. These branches, uniting successively, form a single trunk for each lobe, three for the right and two for the left lung. The vein from the middle lobe of the right lung unites with that from the upper lobe, in most cases forming two trunks on each side, which open separately into the left auricle. Occasionally they remain separate; there are then three veins on the right side. Not unfrequently the two left pulmonary veins terminate by a common opening.

Within the lung, the branches of the pulmonary artery are *in front*, the veins *behind*, and the bronchi *between* the two.

At the root of the lung, the veins are *in front*, the artery *in the middle*, and the bronchus *behind*.

Within the pericardium, their anterior surface is invested by the serous layer of this membrane. The right pulmonary veins pass behind the right auricle and ascending aorta; the left pass in front of the thoracic aorta with the left pulmonary artery.

THE SYSTEMIC VEINS.

The systemic veins may be arranged into three groups: 1. Those of the head and neck, upper extremity, and thorax, which terminate in the superior vena cava. 2. Those of the lower limb, pelvis, and abdomen, which terminate in the inferior vena cava. 3. The cardiac veins, which open directly into the right auricle of the heart.

VEINS OF THE HEAD AND NECK.

The veins of the head and neck may be subdivided into three groups: 1. The veins of the exterior of the head and face. 2. The veins of the neck. 3. The veins of the diploë and interior of the cranium.

Veins of the Exterior of the Head.

The veins of the exterior of the head and face are—the

Frontal.	Temporal.
Supra-orbital.	Internal Maxillary.
Angular.	Temporo-maxillary.
Facial.	Posterior Auricular.
Occipital.	

The **frontal vein** commences on the anterior part of the skull by a venous plexus which communicates with the anterior tributaries of the temporal vein. The veins converge to form a single trunk, which runs downward near the middle line of the forehead parallel with the vein of the opposite side, and unites with it at the root of the nose by a transverse branch called the *nasal arch*. Occasionally the frontal veins join to form a single trunk, which bifurcates at the

FIG. 381.—Veins of the head and neck.

root of the nose into the two angular veins. At the root of the nose the veins diverge, and join the *supra-orbital vein*, at the inner angle of the orbit, to form the *angular vein*.

The **supra-orbital vein** commences on the forehead, communicating with the anterior temporal vein, and runs downward and inward, superficial to the Occipito-frontalis muscle, receiving tributaries from the neighboring structures, and joins the frontal vein at the inner angle of the orbit to form the *angular vein*.

The **angular vein**, formed by the junction of the frontal and supra-orbital veins, runs obliquely downward and outward on the side of the root of the nose and receives the veins of the ala nasi on its inner side and the superior palpebral veins on its outer side; it moreover communicates with the ophthalmic vein, thus

establishing an important anastomosis between this vessel and the cavernous sinus. Some small veins from the dorsum of the nose terminate in the nasal arch.

The **facial vein** commences at the side of the root of the nose, being a direct continuation of the angular vein. It passes obliquely downward and outward beneath the Zygomaticus major and minor muscles, descends along the anterior border of the Masseter, crosses over the body of the lower jaw with the facial artery, and, passing obliquely outward and backward beneath the Platysma and cervical fascia, unites with a branch of communication from the temporo-maxillary vein to form a trunk of large size which enters the internal jugular. From near its termination a communicating branch often runs down the anterior border of the Sterno-mastoid to join the lower part of the anterior jugular.

Tributaries.—The facial vein receives, near the angle of the mouth, communicating tributaries of considerable size (the *deep facial* or *anterior internal maxillary vein*) from the pterygoid plexus. It is also joined by the inferior palpebral, the superior and inferior labial veins, the buccal veins from the cheek, and the masseteric veins. Below the jaw it receives the submental; the inferior palatine, which returns the blood from the plexus around the tonsil and soft palate; the submaxillary vein, which commences in the submaxillary gland; and, generally, the ranine vein.

Surgical Anatomy.—There are some points about the facial vein which render it of great importance in surgery. It is not so flaccid as are most superficial veins, and, in consequence of this, remains more patent when divided. It has, moreover, no valves. It communicates freely with the intracranial circulation, not only at its commencement by its tributaries, the angular and supra-orbital veins, communicating with the ophthalmic vein, a tributary of the cavernous sinus, but also by its deep branch, which communicates through the pterygoid plexus with the cavernous sinus by branches which pass through the foramen ovale and foramen lacerum medium (see page 663). These facts have an important bearing upon the surgery of some diseases of the face, for on account of its patency the facial vein favors septic absorption, and therefore any phlegmonous inflammation of the face following a poisoned wound is liable to set up thrombosis in the facial vein. And on account of its communications with the cerebral sinuses these thrombi are apt to extend upward into them, and detached portions may give rise to purulent foci in other parts of the body, and so induce a fatal issue.

The **Temporal Vein** commences by a minute plexus on the side and vertex of the skull, which communicates with the frontal and supra-orbital veins in front, the corresponding vein of the opposite side, and the posterior auricular and occipital veins behind. From this network anterior and posterior branches are formed which unite above the zygoma, forming the trunk of the vein. This trunk is joined in this situation by a large vein, the *middle temporal*, which receives the blood from the substance of the Temporal muscle and pierces the fascia at the upper border of the zygoma. The temporal vein then descends between the external auditory meatus and the condyle of the jaw, enters the substance of the parotid gland, and unites with the internal maxillary vein to form the temporo-maxillary vein.

Tributaries.—The temporal vein receives in its course some parotid veins, an articular branch from the articulation of the jaw, anterior auricular veins from the external ear, and a vein of large size, the *transverse facial*, from the side of the face. The middle temporal vein, previous to its junction with the temporal vein, receives a branch, the *orbital vein*, which is formed by some external palpebral branches, and passes backward between the layers of the temporal fascia.

The **Internal Maxillary Vein** is a vessel of considerable size, receiving branches which correspond with those of the internal maxillary artery. Thus it receives the middle meningeal veins, the deep temporal, the pterygoid, masseteric, buccal, alveolar, some palatine veins, and the inferior dental. These branches form a large plexus, the *pterygoid*, which is placed between the Temporal and External pterygoid and partly between the Pterygoid muscles. This plexus communicates very freely with the facial vein and with the cavernous sinus by branches through the foramen Vesalii at the base of the skull. The trunk of the vein then passes

backward behind the neck of the lower jaw, and unites with the temporal vein, forming the temporo-maxillary vein.

The **Temporo-Maxillary Vein**, formed by the union of the temporal and internal maxillary veins, descends in the substance of the parotid gland on the outer surface of the external carotid artery, between the ramus of the jaw and the Sterno-mastoid muscle, and divides into two branches, one of which passes inward to join the facial vein; the other is joined by the posterior auricular vein and becomes the external jugular.

The **Posterior Auricular Vein** commences upon the side of the head by a plexus which communicates with the tributaries of the temporal and occipital veins. The vein descends behind the external ear and joins the temporo-maxillary vein, forming the external jugular. This vessel receives the stylo-mastoid vein and some tributaries from the back part of the external ear.

The **Occipital Veins** commence at the back part of the vertex of the skull by a plexus in a similar manner to the other veins. These unite and form one or two veins, which follow the course of the occipital artery, passing deeply beneath the muscles of the back part of the neck, and terminate in the internal jugular, occasionally in the external jugular vein. As these veins pass across the mastoid portion of the temporal bone, one of them receives the mastoid vein, which thus establishes a communication with the lateral sinus.

The Veins of the Neck.

The veins of the neck, which return the blood from the head and face, are—the

External Jugular.	Anterior Jugular.
Posterior External Jugular.	Internal Jugular.
Vertebral.	

The **External Jugular Vein** receives the greater part of the blood from the exterior of the cranium and deep parts of the face, being formed by the junction of the posterior division of the temporo-maxillary and posterior auricular veins. It commences in the substance of the parotid gland, on a level with the angle of the lower jaw, and runs perpendicularly down the neck in the direction of a line drawn from the angle of the jaw to the middle of the clavicle. In its course it crosses the Sterno-mastoid muscle, and runs parallel with its posterior border as far as its attachment to the clavicle, where it perforates the deep fascia, and terminates in the subclavian vein, on the outer side of or in front of the *Scalenus anticus* muscle. In the neck it is separated from the Sterno-mastoid by the anterior layer of the deep cervical fascia, and is covered by the *Platysma*, the superficial fascia, and the integument. This vein is crossed about its middle by the *superficialis colli* nerve, and its upper half is accompanied by the *auricularis magnus* nerve. The external jugular vein varies in size, bearing an inverse proportion to that of the other veins of the neck; it is occasionally double. It is provided with two pairs of valves, the lower pair being placed at its entrance into the subclavian vein, the upper pair in most cases about an inch and a half above the clavicle. The portion of vein between the two sets of valves is often dilated, and is termed the *sinus*. These valves do not prevent the regurgitation of the blood or the passage of injection from below upward.¹

Surgical Anatomy.—Venesection used formerly to be performed on the external jugular vein, but is now probably never resorted to. The anatomical point to be remembered in performing this operation is to cut across the fibres of the *Platysma myoides* in opening the vein, so that by their contraction they will expose the orifice in the vein and so allow the flow of blood.

Tributaries.—This vein receives the occipital occasionally, the posterior external jugular, and near its termination, the suprascapular and transverse cervical veins.

¹ The student may refer to an interesting paper by Dr. Struthers, "On Jugular Venesection in Asphyxia, anatomically and experimentally considered, including the Demonstration of Valves in the Veins of the Neck," in the *Edinburgh Medical Journal* for November, 1856.

It communicates with the anterior jugular, and, in the substance of the parotid, receives a large branch of communication from the internal jugular.

The **Posterior External Jugular Vein** commences in the occipital region, and returns the blood from the integument and superficial muscles in the upper and back part of the neck, lying between the Splenius and Trapezius muscles. It runs down the back part of the neck, and opens into the external jugular just below the middle of its course.

The **Anterior Jugular Vein** commences near the hyoid bone from the convergence of several superficial veins from the submaxillary region. It passes down between the median line and the anterior border of the Sterno-mastoid, and at the lower part of the neck passes beneath that muscle to open into the termination of the external jugular or into the subclavian vein (Fig. 388). This vein varies considerably in size, bearing almost always an inverse proportion to the external jugular. Most frequently there are two anterior jugulars, a right and left, but occasionally only one. This vein receives some laryngeal veins, and occasionally a small thyroid vein. Just above the sternum the two anterior jugular veins communicate by a transverse trunk, which receives tributaries from the inferior thyroid veins. It also communicates with the internal jugular. There are no valves in this vein.

The **Internal Jugular Vein** collects the blood from the interior of the cranium, from the superficial parts of the face, and from the neck. It commences just external to the jugular foramen, at the base of the skull, being formed by the coalescence of the lateral and inferior petrosal sinuses (Fig. 386). At its origin it is somewhat dilated, and this dilatation is called the *sinus*, or *gulf*, of the internal jugular vein. It runs down the side of the neck in a vertical direction, lying at first on the outer side of the internal carotid, and then on the outer side of the common carotid, and at the root of the neck unites with the subclavian vein to form the innominate vein. The internal jugular vein, at its commencement, lies upon the Rectus capitis lateralis, and behind the internal carotid and the nerves passing through the jugular foramen; lower down, the vein and artery lie upon the same plane, the glosso-pharyngeal and hypoglossal nerves passing forward between them; the pneumogastric descends between and behind them in the same sheath, and the spinal accessory passes obliquely outward behind the vein. At the root of the neck the vein of the right side is placed at a little distance from the artery; on the left side it usually lies over the artery at its lower part. The right internal jugular vein crosses the first part of the subclavian artery. The vein is of considerable size, but varies in different individuals, the left one being usually the smaller. It is provided with a pair of valves, which are placed at its point of termination or from half to three-quarters of an inch above it.

Tributaries.—This vein receives in its course the facial, lingual, pharyngeal, superior and middle thyroid veins, and sometimes the occipital. At its point of junction with the branch common to the temporo-maxillary and facial veins it becomes greatly increased in size.

The **lingual veins** commence on the dorsum, sides, and under surface of the tongue, and, passing backward, following the course of the lingual artery and its branches, terminate in the internal jugular. Sometimes the ranine vein, which is a branch of considerable size commencing below the tip of the tongue, joins the lingual. Generally, however, it passes backward, crosses the Hyo-glossus muscle in company with the hypoglossal nerve, and joins the facial.

The **pharyngeal vein** commences in a minute plexus, the *pharyngeal*, at the back part and sides of the pharynx, and, after receiving meningeal tributaries and the Vidian and sphenopalatine veins, terminates in the internal jugular. It occasionally opens into the facial, lingual, or superior thyroid vein.

The **superior thyroid vein** commences in the substance and on the surface of the thyroid gland by tributaries corresponding with the branches of the superior thyroid artery, and terminates in the upper part of the internal jugular vein.

The **middle thyroid vein** collects the blood from the lower part of the lateral lobe of the thyroid gland, and, being joined by some veins from the larynx and trachea, terminates in the lower part of the internal jugular vein.

The **facial and occipital veins** have been described above.

Surgical Anatomy.—The internal jugular vein occasionally requires ligature in cases of septic thrombosis of the lateral sinus from suppuration in the middle ear, in order to prevent embolism of the thoracic viscera. This operation has been performed recently in several cases with the most satisfactory results. The cases are generally those of chronic disease of the middle ear, with discharge of pus which perhaps has existed for many years. The patient is seized with acute septic inflammation, spreading to the mastoid cells, and consequent on this septic thrombosis of the lateral sinus extending to the internal jugular vein. Such cases are always extremely grave, for there is a danger of a portion of the septic clot being detached and causing septic embolism in the thoracic viscera. This may be mechanically prevented by ligature of the internal jugular vein in the middle of the neck. The operation is a comparatively simple one, and may be performed by an incision similar to that employed in ligature of the common carotid artery.

The **Vertebral Vein** commences in the occipital region by numerous small tributaries from the deep muscles at the upper and back part of the neck; these pass outward and enter the foramen in the transverse process of the atlas, and descend, forming a dense plexus around the vertebral artery in the canal formed by the transverse processes of the cervical vertebrae. This plexus unites at the lower part of the neck into two main trunks, one of which emerges from the foramen in the transverse process of the sixth cervical vertebra, and the others through that of the seventh, and, uniting, form a single vessel, which terminates at the root of the neck in the back part of the innominate vein near its origin, its mouth being guarded by a pair of valves. On the right side it crosses the first part of the subclavian artery.

Tributaries.—The vertebral vein receives in its course a vein from the inside of the skull through the posterior condyloid foramen; muscular veins from the muscles in the prevertebral region; dorsi-spinal veins, from the back part of the cervical portion of the spine; meningo-rachidian veins, from the interior of the spinal canal; the anterior and posterior vertebral veins; and close to its termination it is joined by a small vein from the first intercostal space which accompanies the superior intercostal artery.

The **anterior vertebral vein** commences in a plexus around the transverse processes of the upper cervical vertebrae, descends in company with the ascending cervical artery between the Scalenus anticus and Rectus capitis anticus major muscles, and opens into the vertebral vein just before its termination.

The **posterior vertebral vein** (the **deep cervical**) accompanies the profunda cervicis artery, lying between the Complexus and Semispinalis colli. It commences in the suboccipital region by communicating branches from the occipital vein and tributaries from the deep muscles at the back of the neck. It receives tributaries from the plexuses around the spinous processes of the cervical vertebrae, and terminates in the lower end of the vertebral vein.

The Veins of the Diploë.

The diploë of the cranial bones is channelled in the adult by a number of tortuous canals, which are lined by a more or less complete layer of compact tissue.

The veins they contain are large and capacious, their walls being thin, and formed only of endothelium resting upon a layer of elastic tissue, and they present at irregular intervals pouch-like dilatations, or *culs-de-sac*, which serve as reservoirs for the blood. These are the veins of the diploë; they can only be displayed by removing the outer table of the skull.

In adult life, as long as the cranial bones are distinct and separable, these veins are confined to the particular bones; but in old age, when the sutures are united, they communicate with each other and increase in size. These vessels communicate, in the interior of the cranium, with the meningeal veins and with

the sinuses of the dura mater, and on the exterior of the skull with the veins of the pericranium. They are divided into the *frontal*, which opens into the supra-orbital vein by an aperture in the supra-orbital notch; the *anterior temporal*, which is confined chiefly to the frontal bone, and opens into one of the deep temporal veins, after escaping by an aperture in the great wing of the sphenoid;

FIG. 382.—Veins of the Diploë as displayed by the removal of the outer table of the skull.

the *posterior temporal*, which is confined to the parietal bone, and terminates in the lateral sinus by an aperture at the posterior inferior angle of the parietal bone; and the *occipital*, the largest of the four, which is confined to the occipital bone, and opens either into the occipital vein or internally into the lateral sinus or torcular Herophili.

The Cerebral Veins.

The **Cerebral Veins** are remarkable for the extreme thinness of their coats in consequence of the muscular tissue in them being wanting, and for the absence of valves. They may be divided into two sets: the superficial, which are placed on the surface, and the deep veins, which occupy the interior of the organ.

The **Superficial Cerebral Veins** ramify upon the surface of the brain, being lodged in the sulci between the convolutions, a few running across the convolutions. They receive branches from the substance of the brain and terminate in the sinuses. They are named, from the position they occupy, superior, median, and inferior cerebral veins.

The **Superior Cerebral Veins**, eight to twelve in number on each side, return the blood from the convolutions on the superior surface of the hemisphere; they pass forward and inward toward the great longitudinal fissure, where they receive the *median cerebral veins*; near their termination they become invested with a tubular sheath of the arachnoid membrane, and open into the superior longitudinal sinus in the opposite direction to the course of the blood.

The **Median Cerebral Veins** return the blood from the convolutions of the mesial surface of the corresponding hemisphere; they open into the superior cerebral veins, or occasionally into the inferior longitudinal sinus.

The **Inferior Cerebral Veins** ramify on the lower part of the outer and on the under surface of the cerebral hemisphere. Some, collecting tributaries from the under surface of the anterior lobes of the brain, terminate in the cavernous sinus. One vein of large size, the *middle cerebral vein*, commences on the under surface

of the temporo-sphenoidal lobe, and, running along the fissure of Sylvius, opens into the cavernous sinus. Another large vein, the *great anastomotic vein of Trolard*, commences on the parietal lobe, runs along the horizontal limb of the fissure of Sylvius, and opens into the anterior part of the cavernous sinus under the lesser wing of the sphenoid. Others commence on the under surface of the base of the brain, and unite to form from three to five veins, which open into the superior petrosal and lateral sinuses from before backward.

The **Deep Cerebral, or Ventricular Veins** (*venæ Galeni*), are two in number. They are formed by the union of two veins, the *vena corporis striati*, and the *choroid vein*, on either side. They run backward, parallel with one another, between the layers of the velum interpositum, and pass out of the brain at the great transverse fissure, between the posterior extremity, or *splenium*, of the corpus callosum and the tubercula quadrigemina, to enter the straight sinus. The two veins usually unite to form one before opening into the straight sinus.

The *vena corporis striati* commences in the groove between the corpus striatum and thalamus opticus, receives numerous veins from both of these parts, and unites behind the anterior pillar of the fornix with the choroid vein to form one of the *venæ Galeni*.

The *choroid vein* runs along the whole length of the outer border of the choroid plexus, receiving veins from the hippocampus major, the fornix and corpus callosum, and unites, at the anterior extremity of the choroid plexus, with the vein of the corpus striatum.

The **Cerebellar Veins** occupy the surface of the cerebellum, and are disposed in three sets, superior, inferior, and lateral. The *superior* pass forward and inward across the superior vermiciform process, and terminate in the straight sinus; some open into the *venæ Galeni*. The *inferior cerebellar veins*, of large size, run transversely outward, and terminate by two or three trunks in the lateral sinuses. The *lateral anterior cerebellar veins* terminate in the superior petrosal sinuses.

The perivascular lymph-sheaths alluded to above (see page 87) are especially found in connection with the vessels of the brain. These vessels are enclosed in a sheath which acts as a lymphatic channel, through which the lymph is carried to the subarachnoid and subdural spaces, from which it is returned into the general circulation.

The Sinuses of the Dura Mater.

The sinuses of the dura mater are venous channels, analogous to the veins, their outer coat being formed by the dura mater; their inner, by a continuation of the lining membrane of the veins. They are fifteen in number, and are divided into two sets: 1, those situated at the upper and back part of the skull; 2, those at the base of the skull. The former are—the

Superior Longitudinal.	Straight Sinus.
Inferior Longitudinal.	Lateral Sinuses.
Occipital Sinus.	

The **Superior Longitudinal Sinus** occupies the attached margin of the falx cerebri. Commencing at the foramen cæcum, through which it constantly communicates by a small branch with the veins of the nasal fossæ, it runs from before backward, grooving the inner surface of the frontal, the adjacent margins of the two parietal, and the superior division of the crucial ridge of the occipital bone, and terminates by opening into the torcular Herophili. The sinus is triangular in form, narrow in front, and gradually increasing in size as it passes backward. On examining its inner surface it presents the internal openings of the superior cerebral veins, which run, for the most part, from behind forward, and open chiefly at the back part of the sinus, their orifices being concealed by fibrous folds; numerous fibrous bands (*chordæ Willisæ*) are also seen, extending transversely across the inferior angle of the sinus; and, lastly, some small, white, projecting bodies, the *glandule Pacchioni*. This sinus receives the superior cerebral veins, numerous veins from the diploë and dura mater, and, at the posterior extremity

of the sagittal suture, veins from the pericranium, which pass through the parietal foramen.

The *torcular Herophili* is the dilated extremity of the superior longitudinal sinus. It is of irregular form, and is lodged on one side (generally the right) of the internal occipital protuberance. From it the lateral sinus of the side to which it is deflected is derived. It receives also the blood from the occipital sinus.

The **Inferior Longitudinal Sinus**, more correctly described as the *inferior longitudinal vein*, is contained in the posterior part of the free margin of the falx cerebri. It is of a cylindrical form, increases in size as it passes backward, and terminates in the straight sinus. It receives several veins from the falx cerebri, and occasionally a few from the mesial surface of the hemispheres.

The **Straight Sinus** is situated at the line of junction of the falx cerebri with the tentorium. It is triangular in form, increases in size as it proceeds backward, and runs obliquely downward and backward from the termination of the inferior longitudinal sinus to the lateral sinus of the opposite side to that into which the superior longitudinal sinus is prolonged. It communicates by a cross branch

FIG. 383.—Vertical section of the skull, showing the sinuses of the dura mater.

with the torcular Herophili. Beside the inferior longitudinal sinus, it receives the venæ Galeni and the superior cerebellar veins. A few transverse bands cross its interior.

The **Lateral Sinuses** are of large size, and are situated in the attached margin of the tentorium cerebelli. They commence at the internal occipital protuberance, the one, generally the right, being the direct continuation of the superior longitudinal sinus, the other of the straight sinus. They pass horizontally outward to the base of the petrous portion of the temporal bone, then curve downward and inward on each side to reach the jugular foramen, where they terminate in the internal jugular vein. Each sinus rests, in its course, upon the inner surface of the occipital, the posterior inferior angle of the parietal, the mastoid portion of the temporal, and on the occipital, again just before its termination. These sinuses are frequently of unequal size, that formed by the superior longitudinal sinus being the larger, and they increase in size as they proceed from behind forward. The horizontal portion is of a triangular form, the curved portion semicylindrical. Their inner surface is smooth, and not crossed by the fibrous bands found in the other sinuses. These sinuses receive the blood from the superior petrosal sinuses at the base of the petrous portion of the temporal bone, and they unite with the inferior petrosal sinus, just external to the jugular foramen, to form the internal

jugular vein (Fig. 386). They communicate with the veins of the pericranium by means of the mastoid and posterior condyloid veins, and they receive some of the inferior cerebral and inferior cerebellar veins and some veins from the diploë.

The **Occipital** is the smallest of the cranial sinuses. It is generally single, but occasionally there are two. It is situated in the attached margin of the falx cerebelli. It commences by several small veins around the margin of the foramen magnum, one of which joins the termination of the lateral sinus; it communicates with the posterior spinal veins and terminates in the torcular Herophili.

The sinuses at the base of the skull are—the

Cavernous.	Superior Petrosal.
Circular.	Inferior Petrosal.
Transverse.	

The **Cavernous Sinuses** are named from their presenting a reticulated structure. They are two in number, of large size, and placed one on each side of the sella

FIG. 384.—Plan showing the relative position of the structures in the right cavernous sinus, viewed from behind.

turcica, extending from the sphenoidal fissure to the apex of the petrous portion of the temporal bone; they receive anteriorly the ophthalmic vein through the sphenoidal fissure, and open behind into the petrosal sinuses. On the inner wall of each sinus is found the internal carotid artery, accompanied by filaments of the carotid plexus and by the sixth nerve; and on its outer wall, the third, fourth, and ophthalmic division of the fifth nerve. These parts are separated from the blood flowing along the sinus by the lining membrane, which is continuous with the inner coat of the veins. The cavity of the sinus, which is larger behind than in front, is intersected by filaments of fibrous tissue and small vessels. The cavernous sinuses receive some of the cerebral veins; they communicate with the lateral sinuses by means of the superior and inferior petrosal, and with the facial vein through the ophthalmic. They also communicate with each other by means of the circular sinus.

Surgical Anatomy.—An arterio-venous communication may be established between the cavernous sinus and the carotid artery, as it lies in it, giving rise to a pulsating tumor in the orbit. These communications may be the result of injury, such as a bullet wound, a stab, or a blow or fall sufficiently severe to cause a fracture of the base of the skull in this situation, or they may occur idiopathically from the rupture of an aneurism or a diseased condition of the internal carotid artery. The disease begins with sudden noise and pain in the head, followed by exophthalmos, and development of a pulsating tumor at the margin of the orbit, with thrill and the characteristic bruit. In some cases the opposite orbit becomes affected by the passage of the arterial blood into the opposite sinus by means of the circular sinus. Or the arterial blood may find its way through the emissary veins (see page 663) into the pterygoid plexus, and thence into the veins of the face. Pulsating tumors of the orbit may also be due to traumatic aneurism of one of the orbital arteries, and symptoms resembling those of pulsating tumor may be produced by pressure on the ophthalmic vein, as it enters the sinus, by an aneurism of the internal carotid artery.

The **ophthalmic** is a large vein which connects the angular vein at the inner angle of the orbit with the cavernous sinus; it pursues the same course as the ophthalmic artery, and receives tributaries corresponding to the branches derived from that vessel. Forming a short single trunk, it passes through

the inner extremity of the sphenoidal fissure and terminates in the cavernous sinus.

The Inferior Ophthalmic Vein.—Sometimes the veins from the floor of the orbit collect into a separate trunk, the *inferior ophthalmic vein*, which either passes out of the orbit through the sphenomaxillary fissure to join the pterygoid plexus of veins, or else, passing backward through the sphenoidal fissure, it enters the cavernous sinus, either by a separate opening or in common with the ophthalmic vein.

The **Circular Sinus** is formed by two transverse vessels which connect together the two cavernous sinuses, the one passing in front and the other behind the pituitary body, and thus forming with the cavernous sinuses a venous circle around the body. The anterior one is usually the larger of the two, and one or other is occasionally found to be absent.

The **Superior Petrosal Sinus** is situated along the superior border of the petrous portion of the temporal bone, in the front part of the attached margin of the tentorium. It is small and narrow, and connects together the cavernous

FIG. 385.—The sinuses at the base of the skull.

and lateral sinuses at each side. It receives a cerebellar vein (*anterior lateral cerebellar*) from the anterior border of the cerebellum, and a vein from the internal ear.

The **Inferior Petrosal Sinus** is situated in the groove formed by the junction of the posterior border of the petrous portion of the temporal with the basilar process of the occipital. It commences in front at the termination of the cavernous sinus, and behind joins the lateral sinus after it has passed through the jugular foramen, the junction of these two sinuses forming the commencement of the internal jugular vein.

The junction of the two sinuses takes place at the lower border of, or just external to, the jugular foramen. The exact relation of the parts to one another in the foramen is as follows: The inferior petrosal sinus is in front, with the meningeal branch of the ascending pharyngeal artery, and is directed obliquely downward and backward; the lateral sinus is situated at the back part of the fora-

men with a meningeal branch of the occipital artery, and between the two are the glosso-pharyngeal, pneumogastric, and spinal accessory nerves. These three sets of structures are divided from each other by two processes of fibrous tissue. The junction of the sinuses takes place superficial to the nerves, so that these latter lie a little internal to the venous channels in the foramen (see Fig. 386). These sinuses are semicylindrical in form.

The **Transverse Sinus**, or **basilar sinus**, consists of several interlacing veins between the layers of the dura mater over the basilar process of the occipital bone, which serve to connect the two inferior petrosal sinuses. With them the anterior spinal veins communicate.

Emissary Veins.—The emissary veins are vessels which pass through apertures

FIG. 386.—Relation of structures in jugular foramen.

in the cranial wall and establish communications between the sinuses inside the skull and the veins external to it. Some of these are always present, others only occasionally so. They vary much in size in different individuals. The principal emissary veins are the following: 1. A vein, almost always present, which passes through the mastoid foramen and connects the lateral sinus with the posterior auricular or with an occipital vein. 2. A vein which passes through the parietal foramen and connects the superior longitudinal sinus with the veins of the scalp. 3. A plexus of minute veins which pass through the anterior condyloid foramen and connect the occipital sinus with the vertebral vein and deep veins of the neck. 4. An inconstant vein which passes through the posterior condyloid foramen and connects the lateral sinus with the deep veins of the neck. 5. One or two veins of considerable size which pass through the foramen ovale and connect the cavernous sinus with the pterygoid and pharyngeal plexuses. 6. Two or three small veins which pass through the foramen lacerum medium and connect the cavernous sinus with the pterygoid and pharyngeal plexuses. 7. There is sometimes a small

vein passing through the foramen of Vesalius connecting the same parts. 8. A plexus of veins passing through the carotid canal and connecting the cavernous sinus with the internal jugular vein.

FIG. 387.—The superficial veins of the upper extremity.

Surgical Anatomy.—These emissary veins are of great importance in surgery. In addition to them there are, however, other communications between the intra- and extra-cranial circulation, as, for instance, the communication of the angular and supra-orbital veins with the ophthalmic vein at the inner angle of the orbit (page 653), and the communication of the veins of the scalp with the diploic veins (page 658). Through these communications inflammatory processes commencing on the outside of the skull may travel inward, leading to osteo-phlebitis of the diploë and inflammation of the membranes of the brain. To this must be attributed one of the principal dangers of scalp wounds and other injuries of the scalp.

By means of these emissary veins blood may be abstracted almost directly from the intracranial circulation. For instance, leeches applied behind the ear abstract blood almost directly from the lateral sinus through the vein passing through the mastoid foramen. Again, epistaxis in children will frequently relieve severe headache, the blood which flows from the nose being derived from the longitudinal sinus by means of the vein which passes through the foramen cæcum, which is another communication between the intracranial and extracranial circulation which is constantly found in children.

VEINS OF THE UPPER EXTREMITY AND THORAX.

The veins of the Upper Extremity are divided into two sets, *superficial* and *deep*.

The **Superficial Veins** are placed immediately beneath the integument between the two layers of superficial fascia.

The **Deep Veins** accompany the arteries, and constitute the *venæ comites* of those vessels.

Both sets of vessels are provided with valves, which are more numerous in the deep than in the superficial.

The superficial veins of the upper extremity are—the

Superficial veins of the Hand.

Anterior Ulnar.

Posterior Ulnar.

Common Ulnar.

Radial.

Median.

Median Basilic.

Median Cephalic.

Basilic.

Cephalic.

The **Superficial Veins of the Hand and Fingers** are principally situated on the

dorsal surface, and form two plexuses, an inner and outer, on the back of the hand. The inner plexus is formed by the veins from the little finger (*vena salvetella*), the ring finger, and the ulnar side of the middle finger; from it the anterior and posterior ulnar veins are derived. The outer plexus is formed by veins from the thumb, the index finger, and radial side of the middle finger; from it the radial vein is derived. These two plexuses communicate on the back of the hand, forming the superficial arch of veins in this situation. The superficial veins from the palm of the hand form a plexus in front of the wrist, from which the median vein is derived.

The **Anterior Ulnar Vein** commences on the anterior surface of the ulnar side of the hand and wrist, and ascends along the anterior surface of the ulnar side of the forearm to the bend of the elbow, where it joins with the posterior ulnar vein to form the common ulnar. Occasionally it opens separately into the median basilic vein. It communicates with branches of the median vein in front and with the posterior ulnar behind.

The **Posterior Ulnar Vein** commences on the posterior surface of the ulnar side of the wrist. It runs on the posterior surface of the ulnar side of the forearm, and just below the elbow unites with the anterior ulnar vein to form the common ulnar, or else joins the median basilic to form the basilic. It communicates with the deep veins of the palm by a branch which emerges from beneath the *Abductor minimi digiti* muscle.

The **Common Ulnar** is a short trunk which is not constant. When it exists it is formed by the junction of the two preceding veins, and, passing upward and outward, joins the median basilic to form the basilic vein. When it does not exist the anterior and posterior ulnar veins open separately into the median basilic vein.

The **Radial Vein** commences from the dorsal surface of the wrist, communicating with the deep veins of the palm by a branch which passes through the first interosseous space. It forms a large vessel, which ascends along the radial side of the forearm and receives numerous veins from both its surfaces. At the bend of the elbow it unites with the median cephalic to form the cephalic vein.

The **Median Vein** ascends on the front of the forearm, and communicates with the anterior ulnar and radial veins. At the bend of the elbow it receives a branch of communication from the deep veins, and divides into two branches, the median cephalic and median basilic, which diverge from each other as they ascend.

The **Median Cephalic**, usually the smaller of the two, passes outward in the groove between the *Supinator longus* and *Biceps* muscles, and joins with the radial to form the cephalic vein. The branches of the external cutaneous nerve pass beneath this vessel.

The **Median Basilic Vein** passes obliquely inward, in the groove between the *Biceps* and *Pronator radii teres*, and joins the common ulnar to form the basilic. This vein passes in front of the brachial artery, from which it is separated by a fibrous expansion (the *bicipital fascia*) which is given off from the tendon of the *Biceps* to the fascia covering the *Flexor* muscles of the forearm. Filaments of the internal cutaneous nerve pass in front as well as behind this vessel.¹

Venesection is usually performed at the bend of the elbow, and as a matter of practice the largest vein in this situation is commonly selected. This is usually the median basilic, and there are anatomical advantages and disadvantages in selecting this vein. The advantages are, that in addition to its being the largest, and therefore yielding a greater supply of blood, it is the least movable and can be easily steadied on the bicipital fascia on which it rests. The disadvantages are, that it is in close relationship with the brachial artery, separated only by the bicipital fascia; and formerly, when venesection was frequently practised, arterio-venous aneurism was

¹ Cruveilhier says: "Numerous varieties are observed in the disposition of the veins of the elbow; sometimes the common median vein is wanting; but in those cases its two branches are furnished by the radial vein, and the cephalic is almost always in a rudimentary condition. In other cases only two veins are found at the bend of the elbow, the radial and ulnar, which are continuous, without any demarcation, with the cephalic and basilic."

no uncommon result of this practice. Another disadvantage is, that the median basilic is crossed by some of the branches of the internal cutaneous nerve, and these may be divided in the operation, giving rise to "traumatic neuralgia of extreme intensity" (Tillaux).

The **Basilic Vein** is of considerable size, formed by the coalescence of the common ulnar vein with the median basilic. It passes upward along the inner side of the Biceps muscle, pierces the deep fascia a little below the middle of the arm, and, ascending in the course of the brachial artery, terminates by joining the venæ comites of that vessel to form the axillary vein.

The **Cephalic Vein** courses along the outer border of the Biceps muscle, lying in the same groove with the upper external cutaneous branch of the musculo-spiral nerve, to the upper third of the arm; it then passes in the interval between the Pectoralis major and Deltoid muscles, lying in the same groove with the descending branch of the acromial-thoracic artery. It pierces the costo-coracoid membrane, and terminates in the axillary vein just below the clavicle. This vein is occasionally connected with the external jugular or subclavian by a branch which passes from it upward in front of the clavicle.

The **Deep Veins of the Upper Extremity** follow the course of the arteries, forming their venæ comites. They are generally two in number, one lying on each side of the corresponding artery, and they are connected at intervals by short transverse branches.

There are two digital veins accompanying each artery along the sides of the fingers: these, uniting at their base, pass along the interosseous spaces in the palm, and terminate in the two venæ comites which accompany the superficial palmar arch. Branches from these vessels on the radial side of the hand accompany the superficialis volæ, and on the ulnar side terminate in the deep ulnar veins. The deep ulnar veins, as they pass in front of the wrist, communicate with the interosseous and superficial veins, and at the elbow unite with the deep radial veins to form the venæ comites of the brachial artery.

The **Interosseous Veins** accompany the anterior and posterior interosseous arteries. The anterior interosseous veins commence in front of the wrist, where they communicate with the deep radial and ulnar veins; at the upper part of the forearm they receive the posterior interosseous veins, and terminate in the venæ comites of the ulnar artery.

The **Deep Palmar Veins** accompany the deep palmar arch, being formed by tributaries which accompany the ramifications of that vessel. They communicate with the deep ulnar veins at the inner side of the hand, and on the outer side terminate in the venæ comites of the radial artery. At the wrist they receive a dorsal and a palmar tributary from the thumb, and unite with the deep radial veins. Accompanying the radial artery, these vessels terminate in the venæ comites of the brachial artery.

The **Brachial Veins** are placed one on each side of the brachial artery, receiving tributaries corresponding with the branches given off from that vessel; at the lower margin of the axilla they unite with the basilic to form the axillary vein.

These deep veins have numerous anastomoses, not only with each other, but also with the superficial veins.

The **Axillary Vein** is of large size, and formed by the junction of the venæ comites of the brachial artery with the basilic vein. It commences at the lower part of the axillary space, increases in size as it ascends by receiving tributaries corresponding with the branches of the axillary artery, and terminates immediately beneath the clavicle at the lower border of the first rib, where it becomes the subclavian vein. This vessel is covered in front by the Pectoral muscles and costo-coracoid membrane, and lies on the thoracic side of the axillary artery, which it partially overlaps. Near its termination it receives the cephalic vein. This vein is provided with a pair of valves opposite the lower border of the Subscapularis muscle; valves are also found at the termination of the cephalic and subscapular veins.

Surgical Anatomy.—There are several points of surgical interest in connection with the axillary vein. Being more superficial, larger, and slightly overlapping the axillary artery, it is more liable to be wounded in the operation of extirpation of the axillary glands, especially as these glands, when diseased, are apt to become adherent to the vessel. When wounded there is always a danger of air being drawn into its interior, and death resulting. This is due not only to the fact that it is near the thorax, and therefore liable to be influenced by the respiratory movements, but also because it is adherent by its anterior surface to the costo-coracoid membrane, and therefore if wounded is likely to remain patulous and favor the chance of air being sucked in. This adhesion of the vein to the fascia prevents its collapsing, and therefore favors the furious bleeding which takes place in these cases.

To avoid wounding the axillary vein in the extirpation of cancerous glands from the axilla, no sharp cutting instruments should be used after the axillary cavity has been freely exposed, and care should be taken to use no undue force in isolating the glands. Should the vein be so imbedded in the malignant deposit that the latter cannot be removed without taking away a part of the vein, this must be done, the vessel having been first ligatured above and below.

The **Subclavian Vein**, the continuation of the axillary, extends from the lower border of the first rib to the inner end of the sterno-clavicular articulation, where it unites with the internal jugular to form the innominate vein. It is in relation, in front, with the clavicle and Subclavius muscle; behind, with the subclavian artery, from which it is separated internally by the Scalenus anticus muscle and phrenic nerve. Below, it rests in a depression on the first rib and upon the pleura. Above, it is covered by the cervical fascia and integument.

The subclavian vein occasionally rises in the neck to a level with the third part of the subclavian artery, and in two instances has been seen passing with this vessel behind the Scalenus anticus. This vessel is usually provided with valves about an inch from its termination in the innominate, just external to the entrance of the external jugular vein.

Tributaries.—It receives the external and anterior jugular veins and a small branch from the cephalic, outside the Scalenus, and on the inner side of that muscle the internal jugular vein. At the angle of junction with the internal jugular the left subclavian vein receives the thoracic duct, while the right subclavian vein receives the right lymphatic duct.

The **Innominate or Brachio-cephalic Veins** (Fig. 388) are two large trunks, placed one on each side of the root of the neck, and formed by the union of the internal jugular and subclavian veins of the corresponding side.

The **Right Innominate Vein** is a short vessel, an inch in length, which commences at the inner end of the clavicle, and, passing almost vertically downward, joins with the left innominate vein just below the cartilage of the first rib, close to the right border of the sternum, to form the superior vena cava. It lies superficial and external to the innominate artery; on its right side the pleura is interposed between it and the apex of the lung. This vein, at the angle of junction of the internal jugular with the subclavian, receives the right vertebral vein, and, lower down, the right internal mammary, right inferior thyroid, and sometimes the right superior intercostal veins.

The **Left Innominate Vein**, about two and a half inches in length, and larger than the right, passes from left to right across the upper and front part of the chest, at the same time inclining downward, to unite with its fellow of the opposite side, forming the *superior vena cava*. It is in relation, in front, with the first piece of the sternum, from which it is separated by the Sterno-hyoid and Sterno-thyroid muscles, the thymus gland or its remains, and some loose areolar tissue. Behind, it lies across the roots of the three large arteries arising from the arch of the aorta. This vessel is joined by the left vertebral, left internal mammary, left inferior thyroid, and the left superior intercostal veins, and occasionally some thymic and pericardiac veins. There are no valves in the innominate veins.

Peculiarities.—Sometimes the innominate veins open separately into the right auricle; in such cases the right vein takes the ordinary course of the superior vena cava; but the left vein, after communicating by a small branch with the right one, passes in front of the root of the left lung, and, turning to the back of the heart, receives the cardiac veins and terminates in the back of the right auricle. This occasional condition of the veins in the adult is a regular one in the fetus at an early period, and the two vessels are persistent in birds and some mammalia. The

subsequent changes which take place in these vessels are the following: The communicating branch between the two trunks enlarges and forms the future left innominate vein; the remaining part of the left trunk is

obliterated as far as the heart, where it remains pervious and forms the coronary sinus; a remnant of the obliterated vessel is seen in adult life as a fibrous band passing along the back of the left auricle and in front of the root of the left lung, called by Mr. Marshall the *vestigial fold of the pericardium*.

FIG. 388.—The vena cava and azygos veins, with their formative branches.

blood from the first or first and second intercostal spaces, and, passing down-

The **internal mammary veins**, two in number to each artery, follow the course of that vessel, and receive branches corresponding with those derived from it. The two veins of each side unite into a single trunk, which terminates in the innominate vein.

The **inferior thyroid veins**, two, frequently three or four, in number, arise in the venous plexus on the thyroid body, communicating with the middle and superior thyroid veins. The left one descends in front of the trachea behind the Sterno-thyroid muscle, communicating with its fellow by transverse branches, and terminates in the left innominate vein. The right one, which is placed a little to the right of the median line, opens into the right innominate vein just at its junction with the superior vena cava. These veins receive oesophageal, tracheal, and inferior laryngeal veins, and are provided with valves at their termination in the innominate veins.

The **Superior Intercostal Veins** return the blood from the upper intercostal spaces.

The **right superior intercostal**, much smaller than the left, closely corresponds with the superior intercostal artery, receiving the

ward, terminates in the vena azygos major. Occasionally it opens into the right innominate vein.

The *left superior intercostal* is always larger than the right, but varies in size in different subjects, being small when the left upper azygos vein is large, and *vice versa*. It is usually formed by branches from the two or three upper intercostal spaces, and, passing across the arch of the aorta, terminates in the left innominate vein. The left bronchial vein and the left superior phrenic open into it.

The **Superior Vena Cava** receives the blood which is conveyed to the heart from the whole of the upper half of the body. It is a short trunk, varying from two inches and a half to three inches in length, formed by the junction of the two innominate veins. It commences immediately below the cartilage of the first rib close to the sternum on the right side, and, descending vertically, enters the pericardium about an inch and a half above the heart, and terminates in the upper part of the right auricle opposite the upper border of the third left costal cartilage. In its course it describes a slight curve, the convexity of which is turned to the right side.

Relations.—*In front*, with the pericardium and process of cervical fascia which is continuous with it: this separates it from the thymus gland and from the sternum; *behind*, with the root of the right lung; on its *right side*, with the phrenic nerve and right pleura; on its *left side*, with the commencement of the innominate artery and ascending part of the aorta. The portion contained within the pericardium is covered by the serous layer of that membrane in its anterior three-fourths. It receives the vena azygos major just before it enters the pericardium, and several small veins from the pericardium and parts in the mediastinum. The superior vena cava has no valves.

The **Azygos Veins** connect together the superior and inferior venæ cavæ, supplying the place of those vessels in the part of the chest which is occupied by the heart.

The larger, or *right azygos vein* (vena azygos major), commences opposite the first or second lumbar vertebra by a branch from the right lumbar veins (the *ascending lumbar*); sometimes by a branch from the right renal vein or from the inferior vena cava. It enters the thorax through the aortic opening in the Diaphragm, and passes along the right side of the vertebral column to the fourth dorsal vertebra, where it arches forward over the root of the right lung, and terminates in the superior vena cava just before that vessel enters the pericardium. Whilst passing through the aortic opening of the Diaphragm it lies with the thoracic duct on the right side of the aorta, and in the thorax it lies upon the intercostal arteries on the right side of the aorta and thoracic duct, and is partly covered by pleura.

Tributaries.—It receives nine or ten lower intercostal veins of the right side, the vena azygos minor, several œsophageal, mediastinal, and pericardial veins; near its termination, the right bronchial vein; and generally the right superior intercostal vein. A few imperfect valves are found in this vein, but its tributaries are provided with complete valves.

The intercostal veins on the left side, below the two or three upper intercostal spaces, usually form two trunks, named the left lower and the left upper azygos veins.

The *left lower*, or *smaller azygos vein* (vena azygos minor), commences in the lumbar region by a branch from one of the lumbar veins (*ascending lumbar*) or from the left renal. It passes into the thorax through the left crus of the Diaphragm, and, ascending on the left side of the spine as high as the seventh or eighth dorsal vertebra, passes across the column, behind the aorta and thoracic duct, to terminate in the right azygos vein. It receives the four or five lower intercostal veins of the left side, and some œsophageal and mediastinal veins.

The *left upper azygos vein* varies according to the size of the left superior intercostal. It receives veins from the intercostal spaces between the left superior intercostal vein and highest tributary of the left lower azygos. They are usually

two or three in number, and join to form a trunk which ends in the right azygos vein or in the left lower azygos. It sometimes receives the left bronchial vein. When this vein is small or altogether wanting, the left superior intercostal vein will extend as low as the fifth or sixth intercostal space.¹

Surgical Anatomy.—In obstruction of the superior vena cava the azygos veins are one of the principal means by which the venous circulation is carried on, connecting as they do the superior and inferior venæ cavæ, and communicating with the common iliac veins by the ascending lumbar veins, and with many of the tributaries of the inferior vena cava.

The *bronchial veins* return the blood from the substance of the lungs; that of the right side opens into the vena azygos major near its termination; that of the left side, into the left superior intercostal vein or left upper azygos vein.

THE SPINAL VEINS.

The numerous venous plexuses placed upon and within the spine may be arranged into four sets:

1. Those placed on the exterior of the spinal column (the *dorsi-spinal veins*).
2. Those situated in the interior of the spinal canal, between the vertebræ and the theca vertebralis (*meningo-rachidian veins*).
3. The veins of the bodies of the vertebræ (*venæ basis vertebrarum*).
4. The veins of the spinal cord (*medulli-spinal*).

1. The **Dorsi-spinal Veins** commence by small branches which receive their

FIG. 389.—Transverse section of a dorsal vertebra, showing the spinal veins.

blood from the integument of the back of the spine and from the muscles in the vertebral grooves. They form a complicated network, which surrounds the spinous processes, the laminæ, and the transverse and articular processes of all the vertebræ. At the bases of the transverse processes they communicate, by means of ascending and descending branches, with the veins surrounding the contiguous vertebræ, and they join with the veins in the spinal canal by branches which perforate the ligamenta subflava. Other branches pass obliquely forward, between the transverse processes, and communicate with the intraspinal veins through the intervertebral foramina. They terminate by joining the vertebral

¹ For an account of the arrangement of the azygos and superior intercostal veins in a number of consecutive cases from the same dissecting-room, see a paper by Mr. B. G. Morison (*Journal of Anatomy and Physiology*, vol. xiii. p. 346). The most important difference between his description and that in the text is, that he always found two superior intercostal veins on both sides, the vein from the first space being separate, and joining the corresponding innominate vein. The lower (and larger) superior intercostal vein he describes as opening into the azygos on the right and innominate on the left side.

veins in the neck, the intercostal veins in the thorax, and the lumbar and sacral veins in the loins and pelvis.

2. **The Meningo-rachidian Veins.**—The principal veins contained in the spinal canal are situated between the theca vertebralis and the vertebræ. They consist of two longitudinal plexuses, one of which runs along the posterior surface of the bodies of the vertebræ (*anterior longitudinal spinal veins*). The other plexus (*posterior longitudinal spinal veins*) is placed on the inner or anterior surface of the laminæ of the vertebræ.

The *Anterior Longitudinal Spinal Veins* consist of two large, tortuous veins which extend along the whole length of the vertebral column, from the foramen magnum, where they communicate by a venous ring around that opening, to the base of the coccyx, being placed one on each side of the posterior surface of the bodies of the vertebræ along the margin of the posterior common ligament. These veins communicate together opposite each vertebra by transverse trunks which pass beneath the ligament, and receive the large *venæ basis vertebrarum* from the interior of the body of each vertebra. The anterior longitudinal spinal veins are least developed in the cervical and sacral regions. They are not of

FIG. 390.—Vertical section of two dorsal vertebræ, showing the spinal veins.

uniform size throughout, being alternately enlarged and constricted. At the intervertebral foramina they communicate with the dorsi-spinal veins, and with the vertebral veins in the neck, with the intercostal veins in the dorsal region, and with the lumbar and sacral veins in the corresponding regions.

The *Posterior Longitudinal Spinal Veins*, smaller than the anterior, are situated one on each side, between the inner surface of the laminæ and the theca vertebralis. They communicate (like the anterior) opposite each vertebra by transverse trunks, and with the anterior longitudinal veins by lateral transverse branches which pass from behind forward. These veins, by branches which perforate the ligamenta subflava, join with the dorsi-spinal veins. From them branches are given off which pass through the intervertebral foramina and join the vertebral, intercostal, lumbar, and sacral veins.

3. **The Veins of the Bodies of the Vertebræ** (*venæ basis vertebrarum*) emerge from the foramina on their posterior surface, and join the transverse trunk connecting the anterior longitudinal spinal veins. They are contained in large, tortuous channels in the substance of the bones, similar in every respect to those found in the diploë of the cranial bones. These canals lie parallel to the upper and lower surface of the bones. They commence by small openings on the front and sides of the bodies of the vertebræ, through which communicating branches from the veins external to the bone pass into its substance, and converge to the principal canal, which is sometimes double toward its posterior part, and open into the corresponding transverse branch uniting the anterior longitudinal veins. They become greatly developed in advanced age.

4. **The Veins of the Spinal Cord** (*medulli-spinal*) consist of a minute, tortuous,

venous plexus which covers the entire surface of the cord, being situated between the pia mater and arachnoid. These vessels emerge chiefly from the median furrows, and are largest in the lumbar region. Near the base of the skull they unite and form two or three small trunks, which communicate with the vertebral veins, and then terminate in the inferior cerebellar veins or in the inferior petrosal sinuses. Each of the spinal nerves is accompanied by a branch as far as the intervertebral foramina, where they join the other veins from the spinal canal.

There are no valves in the spinal veins.

VEINS OF THE LOWER EXTREMITY, ABDOMEN, AND PELVIS.

The Veins of the Lower Extremity are subdivided, like those of the upper, into two sets, superficial and deep, the superficial veins being placed beneath the integument, between the two layers of superficial fascia, the deep veins accompanying the arteries and forming the *venae comites* of those vessels. Both sets of veins are provided with valves, which are more numerous in the deep than in the superficial set. These valves are also more numerous in the lower than in the upper limb.

The **Superficial Veins of the Lower Extremity** are the *internal* or *long saphenous* and the *external* or *short saphenous*.

On the dorsum of the foot is a venous arch situated in the superficial structures over the anterior extremities of the metatarsal bones. It has its convexity directed forward, and receives digital tributaries from the upper surface of the toes; at its concavity it is joined by numerous small veins which form a plexus on the dorsum of the foot. The arch terminates internally in the long saphenous, externally in a short saphenous vein.

The **internal or long saphenous vein** (Fig. 391) commences at the inner side of the arch on the dorsum of the foot; it ascends in front of the inner malleolus and along the inner side of the leg, behind the inner margin of the tibia, accompanied by the internal saphenous nerve. At the knee it passes backward behind the inner condyle of the femur, ascends along the inside of the thigh, and, passing through the saphenous opening in the fascia lata, terminates in the femoral vein about an inch and a half below Poupart's ligament. This vein receives in its course cutaneous tributaries from the leg and thigh, and at the saphenous opening the superficial epigastric, superficial circumflex iliac, and external pudic veins. The veins from the inner and back part of the thigh frequently unite to form a large vessel, which enters the main trunk near the saphenous opening; and sometimes those on the outer side of the thigh join to form another large vessel; so that occasionally three large veins are seen converging from different parts of the thigh toward the saphenous opening. The internal saphenous vein communicates in the foot with the internal plantar vein; in the leg, with the posterior tibial veins by branches which perforate the tibial origin of the Soleus muscle, and also with the anterior tibial veins; at the knee, with the articular veins; in the thigh, with the femoral vein by one or more branches. The valves in this vein vary from two to six in number; they are more numerous in the thigh than in the leg.

The **external or short saphenous vein** (Fig. 392) commences at the outer side of the arch on the dorsum of the foot; it ascends behind the outer malleolus, and along the outer border of the tendo Achillis, across which it passes at an acute angle to reach the middle line of the posterior aspect of the leg. Passing directly upward, it perforates the deep fascia in the lower part of the popliteal space, and terminates in the popliteal vein, between the heads of the Gastrocnemius muscle.¹ It receives numerous large tributaries from the back part of

¹ Mr. Gay calls attention to the fact that the external saphenous vein often (he says invariably) penetrates the fascia at or about the point where the tendon of the Gastrocnemius commences, and runs below the fascia in the rest of its course, or sometimes among the muscular fibres, to join the popliteal vein. (See Gay on *Varicose Disease of the Lower Extremities*, p. 24, where there is also a careful and elaborate description of the branches of the saphenous veins.)

the leg, and communicates with the deep veins on the dorsum of the foot and behind the outer malleolus. Before it perforates the deep fascia it gives off

a communicating branch, which passes upward and inward to join the internal saphenous vein. This vein has a variable number of valves, from three to nine (Gay), one of which is always found near its termination in the popliteal vein. The external saphenous nerve lies close beside this vein.

FIG. 391.—The internal or long saphenous vein and its branches.

Surgical Anatomy.—The saphena veins are of considerable surgical importance, since a varicose condition of these vessels is more frequently met with than those in other parts of the body, except perhaps the spermatic and hæmorrhoidal veins. The course of the internal saphenous is in front of the tip of the malleolus, over the subcutaneous surface of the lower end of the tibia, and then along the internal border of this bone to the back part of the internal condyle of the femur, whence it follows the course of the Sartorius muscle, and is represented on the surface by a line drawn from the posterior border of the Sartorius on a level with the internal condyle to the saphenous opening. The short saphenous lies behind the external malleolus, and from this follows the middle line of the calf to just below the ham. It is not generally so apparent beneath the skin as the internal saphenous. Both these veins in the leg are accompanied by nerves, the internal saphenous being joined by its companion nerve just below the level of the knee-joint. No doubt much of the pain of varicose veins in the leg is due to this fact. On the Continent the internal saphenous vein as it rests on the tibia just above the malleolus is sometimes selected for venesection.

FIG. 392.—External or short saphenous vein.

The Deep Veins of the Lower Extremity accompany the arteries and their branches, and are called the *venæ comites* of those vessels.

The external and internal plantar veins unite to form the posterior tibial. They accompany the posterior tibial artery and are joined by the *peroneal veins*.

The anterior tibial veins are formed by a continuation upward of the *venæ comites* of the dorsalis pedis artery. They pass between the tibia and fibula, through the large oval aperture above the interosseous membrane, and form, by their junction with the posterior tibial, the popliteal vein.

The valves in the deep veins are very numerous.

The Popliteal Vein is formed by the junction of the *venæ comites* of the anterior and posterior tibial vessels; it ascends through the popliteal space to the tendinous aperture in the Adductor magnus, where it becomes the femoral vein. In the lower part of its course it is placed internal to the artery; between the

heads of the Gastrocnemius it is superficial to that vessel; but above the knee-joint it is close to its outer side. It receives the sural veins from the Gastrocnemius muscle, the articular veins, and the external saphenous. The valves in this vein are usually four in number.

The **Femoral Vein** accompanies the femoral artery through the upper two-thirds of the thigh. In the lower part of its course it lies external to the artery; higher up it is behind it; and at Poupart's ligament it lies to its inner side and on the same plane. It receives numerous muscular tributaries: the profunda femoris and deep external pudic veins join it near Poupart's ligament and about an inch and a half below the internal saphenous vein. The valves in this vein are four or five in number.

The **External Iliac Vein** commences at the termination of the femoral, beneath the crural arch, and, passing upward along the brim of the pelvis, terminates opposite the sacro-iliac synchondrosis by uniting with the internal iliac to form the common iliac vein. On the right side it lies at first along the inner side of the external iliac artery, but as it passes upward gradually inclines behind it. On the left side it lies altogether on the inner side of the artery. It receives, immediately above Poupart's ligament, the deep epigastric and deep circumflex iliac veins and a small pubic vein, corresponding to the pubic branch of the obturator artery. According to Friedreich, it frequently contains one, and sometimes two valves.

The Deep Epigastric Veins.—Two veins accompany the deep epigastric artery; they usually unite into a single trunk before their termination in the external iliac vein.

The Deep Circumflex Iliac Veins.—Two veins accompany the deep circumflex iliac artery. These unite into a single trunk which crosses the external iliac artery just above Poupart's ligament and terminates in the external iliac vein.

The **Internal Iliac Vein** is formed by the *venæ comites* of the branches of the internal iliac artery, the umbilical arteries excepted. It receives the blood from the exterior of the pelvis by the gluteal, sciatic, internal pudic, and obturator veins, and from the organs in the cavity of the pelvis by the hæmorrhoidal and vesico-prostatic plexuses in the male, and the uterine and vaginal plexuses in the female. The vessels forming these plexuses are remarkable for their large size, their frequent anastomoses, and the number of valves which they contain. The internal iliac vein lies at first on the inner side, and then behind the internal iliac artery, and terminates opposite the sacro-iliac articulation by uniting with the external iliac to form the common iliac vein. This vessel has no valves.

The **internal pudic veins** (*venæ comites*) have the same course as the internal pudic artery. They receive tributaries corresponding to the branches of the artery, except the tributary corresponding to the dorsal artery of the penis; that is, the dorsal vein of the penis, which opens into the prostatic plexus.

The **hæmorrhoidal plexus** surrounds the lower end of the rectum, being formed by the superior hæmorrhoidal veins (tributaries of the inferior mesenteric), and the middle and inferior hæmorrhoidal, which terminate in the internal iliac. The portal and general venous systems have a free communication by means of the branches composing this plexus.

Surgical Anatomy.—The veins of this plexus are apt to become dilated and varicose and form piles. This is partly due to the free communication between the portal and systemic circulation which here exists, so that any obstruction to the flow of blood through either the inferior vena cava or its main tributaries, or through the portal vein, tends to produce passive congestion of this plexus. The condition is also partly due to the fact that the vessels are contained in very loose, lax connective tissue, so that they get less support from surrounding structures than most other veins, and are less capable of resisting increased blood-pressure. And, finally, the condition is favored by gravitation, inasmuch as the portal vein contains no valves.

The **vesico-prostatic plexus** surrounds the neck and base of the bladder and prostate gland. It communicates with the hæmorrhoidal plexus behind, and receives the dorsal vein of the penis, which enters the pelvis beneath the subpubic ligament. This plexus is supported upon the sides of the bladder by a reflection of the pelvic fascia. The veins composing it are very liable to become varicose, and often contain hard, earthy concretions, called *phleboliths*.

Surgical Anatomy.—This plexus is wounded in the lateral operation of lithotomy, and it is through it that septic matter finds its way into the general circulation after this operation.

The **dorsal vein of the penis** is a vessel of large size which returns the blood from the body of that organ. At first it consists of two branches, which are contained in the groove on the dorsum of the penis, and it receives veins from the glans, the corpus spongiosum, and numerous superficial veins; these unite near the root of the penis into a single trunk, which passes through the suspensory ligament of the penis, pierces the triangular ligament beneath the pubic arch, and divides into two branches, which enter the prostatic plexus.

The **vaginal plexus** surrounds the mucous membrane, being especially developed at the orifice of the vagina; it communicates with the vesical plexus in front, and with the hæmorrhoidal plexus behind.

The **uterine plexus** is situated along the sides and superior angles of the uterus, between the layers of the broad ligament, receiving large venous canals (the *uterine sinuses*) from the substance of the uterus. The veins composing this plexus anastomose frequently with each other and with the ovarian veins. They are not tortuous like the arteries.

The **Common Iliac Veins** are formed by the union of the external and internal iliac veins in front of the sacro-iliac articulation: passing obliquely upward toward the right side, they terminate upon the intervertebral substance between the fourth and fifth lumbar vertebræ, where the veins of the two sides unite at an acute angle to form the inferior vena cava. The *right common iliac* is shorter than the left, nearly vertical in its direction, and ascends behind and then to the outer side of its corresponding artery. The *left common iliac*, longer and more oblique in its course, is at first situated on the inner side of the corresponding artery, and then behind the right common iliac. Each common iliac receives the ilio-lumbar, and sometimes the lateral sacral, veins. The left receives, in addition, the middle sacral vein. No valves are found in these veins.

The **middle sacral veins** accompany the corresponding artery along the front of the sacrum, and terminate in the left common iliac vein; occasionally in the angle of junction of the two iliac veins.

Peculiarities.—The left common iliac vein, instead of joining with the right in its usual position, occasionally ascends on the left side of the aorta as high as the kidney, where, after receiving the left renal vein, it crosses over the aorta, and then joins with the right vein to form the vena cava. In these cases the two common iliacs are connected by a small communicating branch at the spot where they are usually united.¹

The **Inferior Vena Cava** returns to the heart the blood from all the parts below the Diaphragm. It is formed by the junction of the two common iliac veins on the right side of the intervertebral substance between the fourth and fifth lumbar vertebræ. It passes upward along the front of the spine on the right side of the aorta, and, having reached the under surface of the liver, is contained in a groove in its posterior surface. It then perforates the central tendon of the Diaphragm, enters the pericardium, where it is covered by its serous layer, and terminates in the lower and back part of the right auricle. At its termination in the auricle it is provided with a valve, the *Eustachian*, which is of large size during fetal life.

Relations.—*In front*, from below upward, with the mesentery, right spermatic artery, transverse portion of the duodenum, the pancreas, portal vein, and the

¹ See two cases which have been described by Mr. Walsham in the *St. Bartholomew's Hospital Reports*, vols. xvi. and xvii.

posterior surface of the liver, which partly and occasionally completely surrounds it; *behind*, with the vertebral column, the right crus of the Diaphragm, the right renal and lumbar arteries, right semilunar ganglion; on the *left side*, with the aorta.

Tributaries.—It receives in its course the following veins:

Lumbar.	Suprarenal.
Right Spermatic.	Phrenic.
Renal.	Hepatic.

Peculiarities.—*In Position.*—This vessel is sometimes placed on the left side of the aorta, as high as the left renal veins, after receiving which it crosses over to its usual position on the right side; or it may be placed altogether on the left side of the aorta, as far upward as its termination in the heart: in such cases the abdominal and thoracic viscera, together with the great vessels, are all transposed.

Point of Termination.—Occasionally the inferior vena cava joins the right azygos vein, which is then of large size. In such cases the superior cava receives the whole of the blood from the body before transmitting it to the right auricle, except the blood from the hepatic veins, which passes directly into the right auricle.

The **lumbar veins**, four in number on each side, collect the blood by dorsal tributaries from the muscles and integument of the loins and by abdominal tributaries from the walls of the abdomen, where they communicate with the epigastric veins. At the spine they receive veins from the spinal plexuses, and then pass forward, round the sides of the bodies of the vertebræ beneath the Psoas magnus, and terminate at the back part of the inferior cava. The left lumbar veins are longer than the right, and pass behind the aorta. The lumbar veins are connected together by a longitudinal vein which passes in front of the transverse processes of the lumbar vertebræ, and is called the *ascending lumbar*. It forms the most frequent origin of the corresponding vena azygos, and serves to connect the common iliac, ilio-lumbar, lumbar, and azygos veins of the corresponding side of the body.

The **spermatic veins** emerge from the back of the testis, and receive tributaries from the epididymis; they unite and form a convoluted plexus called the *spermatic plexus* (*plexus pampiniformis*), which forms the chief mass of the cord: the vessels composing this plexus are very numerous, and ascend along the cord in front of the vas deferens; below the external abdominal ring they unite to form three or four veins, which pass along the spermatic canal, and, entering the abdomen through the internal abdominal ring, coalesce to form two veins, which ascend on the Psoas muscle behind the peritoneum, lying one on each side of the spermatic artery, and unite to form a single vein, which opens on the right side into the inferior vena cava at an acute angle; on the left side into the left renal vein at a right angle. The spermatic veins are provided with valves.¹ The left spermatic vein passes behind the sigmoid flexure of the colon, and is thus exposed to pressure from the contents of that bowel.

Surgical Anatomy.—The spermatic veins are very frequently varicose, constituting the disease known as varicocele. Though it is quite possible that the originating cause of this affection may be a congenital abnormality either in the size or number of the veins of the pampiniform plexus, still it must be admitted that there are many anatomical reasons why these veins should become varicose—viz. the imperfect support afforded to them by the loose tissue of the scrotum; their great length; their vertical course; their dependent position; their plexiform arrangement in the scrotum, with their termination in one small vein in the abdomen; their few and imperfect valves; and the fact that they may be subjected to pressure in their passage through the abdominal wall.

The **ovarian veins** are analogous to the spermatic in the male; they form a plexus near the ovary and in the broad ligament and Fallopian tube, communicating with the uterine plexus. They terminate in the same way as the spermatic veins in the male. Valves are occasionally found in these veins. These vessels, like the uterine veins, become much enlarged during pregnancy.

¹ Rivington has pointed out that a valve is usually found at the orifices of both the right and left spermatic veins. When no valves exist at the opening of the left spermatic vein into the left renal vein, valves are generally present in the left renal vein within a quarter of an inch from the orifice of the spermatic vein (*Journal of Anatomy and Physiology*, vol. vii. p. 163).

The **renal veins** are of large size, and placed in front of the renal arteries.¹ The left is longer than the right, and passes in front of the aorta, just below the origin of the superior mesenteric artery. It receives the left spermatic, the left inferior phrenic, and, generally, the left suprarenal veins. It opens into the vena cava a little higher than the right.

The **suprarenal veins** terminate, on the right side, in the vena cava; on the left side, in the left renal or phrenic vein.

The **phrenic veins** follow the course of the phrenic arteries. The *two superior*, of small size, accompany the phrenic nerve and comes nervi phrenici artery, and join the internal mammary. The *two inferior phrenic veins* follow the course of the phrenic arteries, and terminate, the right in the inferior vena cava, the left in the left renal vein.

The **hepatic veins** commence in the substance of the liver, in the capillary terminations of the portal vein and hepatic artery: these tributaries, gradually uniting, usually form three large veins, which converge toward the posterior surface of the liver and open into the inferior vena cava, whilst that vessel is situated in the groove at the back part of this organ. Of these three veins, one from the right, and another from the left lobe, open obliquely into the inferior vena cava, that from the middle of the organ and lobulus Spigelii having a straight course. The hepatic veins run singly, and are in direct contact with the hepatic tissue. They are destitute of valves.

The Portal System of Veins.

The portal venous system is composed of four large veins which collect the venous blood from the viscera of digestion. The trunk formed by their union (*vena portæ*) enters the liver and ramifies throughout its substance, and its branches, again emerging from that organ as the hepatic veins, terminate in the inferior vena cava. The branches in this vein are in all cases single and destitute of valves.

The veins forming the portal system are—the

Superior Mesenteric.	Inferior Mesenteric.
Splenic.	Gastric.

The **superior mesenteric vein** returns the blood from the small intestines and from the cæcum and ascending and transverse portions of the colon, corresponding with the distribution of the branches of the superior mesenteric artery. The large trunk formed by the union of these branches ascends along the right side and in front of the corresponding artery, passes in front of the transverse portion of the duodenum, and unites, behind the upper border of the pancreas, with the splenic vein to form the vena portæ. It receives the right gastro-epiploic vein.

The **splenic vein** commences by five or six large branches which return the blood from the substance of the spleen. These, uniting, form a single vessel, which passes from left to right, grooving the upper and back part of the pancreas below the artery, and terminates at its greater end by uniting at a right angle with the superior mesenteric to form the vena portæ. The splenic vein is of large size, and not tortuous like the artery. It receives the vasa brevia from the left extremity of the stomach, the left gastro-epiploic vein, pancreatic branches from the pancreas, the pancreatico-duodenal vein, and the inferior mesenteric vein.

The **inferior mesenteric vein** returns the blood from the rectum, sigmoid flexure, and descending colon, corresponding with the ramifications of the branches of the inferior mesenteric artery. Ascending beneath the peritoneum in the lumbar region, it passes behind the transverse portion of the duodenum and pancreas and terminates in the splenic vein. Its hæmorrhoidal branches inosculate with those

¹ The student may observe that all veins above the Diaphragm, which do not lie on the same plane as the arteries which they accompany, lie in front of them, and that all veins below the Diaphragm, which do not lie on the same plane as the arteries which they accompany, lie behind them, except the renal and profunda femoris vein.

of the internal iliac, and thus establish a communication between the portal and the general venous system.¹

The **gastric veins** are two in number: one, a small vein, corresponds to the pyloric branch of the hepatic artery; the other, considerably larger, corresponds to the gastric artery. The former (*pyloric*, Walsham) runs along the lesser cur-

FIG. 393.—Portal vein and its branches.

NOTE.—In this diagram the right gastro-epiploic vein opens into the splenic vein; generally it empties itself into the superior mesenteric, close to its termination.

vature of the stomach toward the pyloric end, receives branches from the pylorus and duodenum, and ends in the vena portæ. The latter (*coronary*, Walsham) begins near the pylorus, runs along the lesser curvature of the stomach toward the

¹ Besides this anastomosis between the portal vein and the branches of the vena cava, other anastomoses between the portal and systemic veins are formed by the communication between the gastric veins and the esophageal veins, which empty themselves into the vena azygos minor; between the left renal vein and the veins of the intestines, especially of the colon and duodenum; between the veins of the round ligament of the liver and the portal veins; and between the superficial branches of the portal veins of the liver and the phrenic veins, as pointed out by Mr. Kiernan. (See *Physiological Anatomy*, by Todd and Bowman, 1859, vol. ii. p. 348.)

œsophageal opening, and then curves downward and backward between the folds of the lesser omentum, to end in the vena portæ.

The **Portal Vein** is formed by the junction of the superior mesenteric and splenic veins, their union taking place in front of the vena cava and behind the upper border of the great end of the pancreas. Passing upward through the right border of the lesser omentum to the under surface of the liver, it enters the transverse fissure, where it is somewhat enlarged, forming the *sinus* of the portal vein, and divides into two branches which accompany the ramifications of the hepatic artery and hepatic duct throughout the substance of the liver. Of these two branches, the right is the larger, but the shorter, of the two. The portal vein is about three or four inches in length, and, whilst contained in the lesser omentum, lies behind and between the hepatic duct and artery, the former being to the right, the latter to the left. These structures are accompanied by filaments of the hepatic plexus of nerves and numerous lymphatics, surrounded by a quantity of loose areolar tissue (*capsule of Glisson*), and placed between the layers of the lesser omentum. The vena portæ receives the gastric and cystic veins: the latter vein sometimes terminates in the right branch of the vena portæ. Within the liver the portal vein receives the blood from the branches of the hepatic artery.

THE CARDIAC VEINS.

The veins which return the blood from the substance of the heart are—the

Anterior Cardiac Vein.	Right Cardiac Veins.
Posterior Cardiac Vein.	Right or Small Coronary Sinus.
Left Cardiac Veins.	Left or Great Coronary Sinus.
Venæ Thebesii.	

The **Anterior Cardiac Vein** (sometimes called *Great Cardiac Vein*) is a vessel of considerable size which commences at the apex of the heart and ascends along the anterior interventricular groove to the base of the ventricles. It then curves to the left side, around the auriculo-ventricular groove, between the left auricle and ventricle, to the back part of the heart, and opens into the great coronary sinus, its aperture being guarded by two valves. It receives, in its course, tributaries from both ventricles, but especially the left, and also from the left auricle; one of these, ascending along the thick margin of the left ventricle, is of considerable size. The vessels joining it are provided with valves.

The **Posterior Cardiac Vein** commences by small tributaries at the apex of the heart, communicating with those of the preceding. It ascends along the posterior interventricular groove to the base of the heart, and terminates in the great coronary sinus, its orifice being guarded by a valve. It receives the veins from the posterior surface of both ventricles.

The **Left Cardiac Veins** are three or four small vessels which collect the blood from the posterior surface of the left ventricle, and open into the lower border of the great coronary sinus.

The **Right Cardiac Veins** are three or four small vessels which collect the blood from the anterior surface of the right ventricle. One of these (the *vein of Galen*), larger than the rest, runs along the right border of the heart. They open separately into the lower part of the right auricle.

The **Right or Small Coronary Sinus** runs along the groove between the right auricle and ventricle, to open into the right extremity of the great coronary sinus. It receives blood from the back part of the right auricle and ventricle.

The **Left or Great Coronary Sinus** is that portion of the anterior cardiac vein which is situated in the posterior part of the left auriculo-ventricular groove. It is about an inch in length, presents a considerable dilatation, and is covered by the muscular fibres of the left auricle. It receives the veins enumerated above, and an *oblique vein* from the back part of the left auricle, the remnant of the obliterated left innominate trunk of the fœtus, described by Mr. Marshall. The

great coronary sinus terminates in the right auricle between the inferior vena cava and the auriculo-ventricular aperture, its orifice being guarded by a semilunar fold of the lining membrane of the heart, the *coronary valve*. All the veins joining this vessel, excepting the oblique vein above mentioned, are provided with valves.

The **Venæ Thebesii** are numerous minute veins, which return the blood directly from the muscular substance, without entering the venous current. They open by minute orifices (*foramina Thebesii*) on the inner surface of the right auricle.

THE LYMPHATICS.

THE Lymphatics have derived their name from the appearance of the fluid contained in their interior (*lymp^ha*, water). They are also called *absorbents*, from the property they possess of absorbing certain materials from the tissues and conveying them into the circulation.

The lymphatic system includes not only the lymphatic vessels and the glands through which they pass, but also the *lacteal* or *chyliferous vessels*. The lacteals are the lymphatic vessels of the small intestine, and differ in no respect from the lymphatics generally, excepting that they contain a milk-white fluid, the *chyle*, during the process of digestion, and convey it into the blood through the thoracic duct.

The lymphatics are exceedingly delicate vessels, the coats of which are so transparent that the fluid they contain is readily seen through them. They retain a nearly uniform size, being interrupted at intervals by constrictions, which give them a knotted or beaded appearance. These constrictions are due to the presence of valves in their interior. Lymphatics have been found in nearly every texture and organ of the body which contain blood-vessels. Such non-vascular structures as cartilage, the nails, cuticle, and hair have none, but with these exceptions it is probable that eventually all parts will be found to be permeated by these vessels.

The lymphatics are arranged into a superficial and deep set. The superficial lymphatics, on the surface of the body, are placed immediately beneath the integument, accompanying the superficial veins: they join the deep lymphatics in certain situations by perforating the deep fascia. In the interior of the body they lie in the submucous areolar tissue throughout the whole length of the gastro-pulmonary and genito-urinary tracts, and in the subserous tissue in the cranial, thoracic, and abdominal cavities. The method of their origin has been described along with the other details of their minute anatomy (page 86). Here it will be sufficient to say that a plexiform network of minute lymphatics may be found interspersed among the proper elements and blood-vessels of the several tissues, the vessels composing which, as well as the meshes between them, are much larger than those of the capillary plexus. From these networks small vessels emerge, which pass either to a neighboring gland or to join some larger lymphatic trunk. The deep lymphatics, fewer in number and larger than the superficial, accompany the deep blood-vessels. Their mode of origin is probably similar to that of the superficial vessels. The lymphatics of any part or organ exceed the veins in number, but in size they are much smaller. Their anastomoses also, especially those of the large trunks, are more frequent, and are effected by vessels equal in diameter to those which they connect, the continuous trunks retaining the same diameter.

The **lymphatic** or **absorbent glands**, named also *conglobate glands*, are small, solid, glandular bodies situated in the course of the lymphatic and lacteal vessels. In size they vary from a hemp-seed to an almond, and their color, on section, is of a pinkish-gray tint, excepting the bronchial glands, which in the adult are mottled with black. Each gland has a layer or capsule of cellular tissue investing it, from which prolongations dip into its substance, forming partitions. The lymphatic and lacteal vessels pass through these bodies in their passage to the thoracic and lymphatic ducts. A lymphatic or lacteal vessel, previous to

entering a gland, divides into several small branches, which are named *afferent vessels*. As they enter their external coat becomes continuous with the capsule of the gland, and the vessels, much thinned, and consisting only of their internal or endothelial coat, pass into the gland, and branch out upon and in the tissue of the capsule, these branches opening into the lymph-sinuses of the gland. From these sinuses fine branches proceed to form a plexus, the vessels of which unite to form a single *efferent vessel*, which, on emerging from the gland, is again invested with an external coat. (Further details on the minute anatomy of the lymphatic vessels and glands will be found in the chapter on General Anatomy.)

THE THORACIC DUCT.

The thoracic duct (Fig. 394) conveys the great mass of lymph and chyle into the blood. It is the common trunk of all the lymphatic vessels of the body, excepting those of the right side of the head, neck, and thorax, and right upper extremity, the right lung, right side of the heart, and the convex surface of the liver. It varies in length from fifteen to eighteen inches in the adult, and extends from the second lumbar vertebra to the root of the neck. It commences in the abdomen by a triangular dilatation, the *receptaculum chyli* (reservoir or cistern of Pecquet), which is situated upon the front of the body of the second lumbar vertebra, to the right side and behind the aorta, by the side of the right crus of the Diaphragm. It ascends into the thorax through the aortic opening in the Diaphragm, lying to the right of the aorta, and is placed in the posterior mediastinum in front of the vertebral column, lying between the aorta and vena azygos major. Opposite the fourth dorsal vertebra it inclines toward the left

FIG. 394.—The thoracic and right lymphatic duct.

side, and ascends behind the arch of the aorta on the left side of the oesophagus, and behind the first portion of the left subclavian artery, to the upper orifice of the thorax. Opposite the seventh cervical vertebra it turns outward and then curves downward over the subclavian artery and in front of the Scalenus anticus muscle, so as to form an arch, and terminates in the left

subclavian vein at its angle of junction with the left internal jugular vein. The thoracic duct, at its commencement, is about equal in size to the diameter of a goosequill, diminishes considerably in its calibre in the middle of the thorax, and is again dilated just before its termination. It is generally flexuous in its course, and constricted at intervals so as to present a varicose appearance. The thoracic duct not unfrequently divides in the middle of its course into two branches of unequal size, which soon reunite, or into several branches, which form a plexiform interlacement. It occasionally divides, at its upper part, into two branches, of which the one on the left side terminates in the usual manner, while that on the right opens into the right subclavian vein, in connection with the right lymphatic duct. The thoracic duct has numerous valves throughout its whole course, but they are more numerous in the upper than in the lower part: at its termination it is provided with a pair of valves, the free borders of which are turned toward the vein, so as to prevent the passage of venous blood into the duct.

Tributaries.—The thoracic duct, at its commencement, receives four or five large trunks from the abdominal lymphatic glands, and also the trunk of the lacteal vessels. Within the thorax it is joined by the lymphatic vessels from the left half of the wall of the thoracic cavity, the lymphatics from the sternal and intercostal glands, those of the left lung, left side of the heart, trachea, and œsophagus; and, just before its termination, it receives the lymphatics of the left side of the head and neck and left upper extremity.

Structure (Fig. 61).—The thoracic duct is composed of three coats, which differ in some respects from those of the lymphatic vessels. The *internal coat* consists of a single layer of flattened lanceolate-shaped endothelial cells with serrated borders; of a subendothelial layer, similar to that found in the arteries; and an elastic fibrous coat, the fibres of which run in a longitudinal direction. The *middle coat* consists of a longitudinal layer of white connective tissue with elastic fibres, external to which are several laminae of muscular tissue, the fibres of which are for the most part disposed transversely, but some are oblique or longitudinal and intermixed with elastic fibres. The *external coat* is composed of areolar tissue, with elastic fibres and isolated fasciculi of muscular fibres.

The **Right Lymphatic Duct** is a short trunk, about half an inch in length and a line or a line and a half in diameter. It terminates in the right subclavian vein at its angle of junction with the right internal jugular vein. Its orifice is guarded by two semilunar valves, which prevent the passage of venous blood into the duct.

Tributaries.—It receives the lymph from the right side of the head and neck, the right upper extremity, the right side of the thorax, the right lung and right side of the heart, and from part of the convex surface of the liver.

LYMPHATICS OF THE HEAD, FACE, AND NECK.

The **Lymphatic Glands of the Head** (Fig. 395) are of small size, few in number, and confined to its posterior region. They are the *occipital* and *posterior auricular*. The *occipital set* are placed at the back of the head along the attachment of the Occipito-frontalis muscle. The *posterior auricular set* are placed near the upper end of the Sterno-mastoid muscle. Both these sets of glands are affected in cutaneous eruptions and other diseases of the scalp. In the face the superficial lymphatic glands are more numerous: they are the *parotid*, some of which are superficial, and others deeply placed in the substance of the parotid gland; the *zygomatic*, situated under the zygoma; the *buccal*, on the surface of the Buccinator muscle; and the *internal maxillary*, the largest, beneath the ramus of the lower jaw.

The **lymphatic vessels of the scalp** are divided into an *anterior* and a *posterior set*, which follow the course of the temporal and occipital vessels. The *temporal set* accompany the temporal artery in front of the ear, to the parotid lymphatic glands, from which they proceed to the lymphatic glands of the neck. The *occipital set* follow the course of the occipital artery, descend to the occipital

and posterior auricular lymphatic glands, and from thence join the cervical glands.

The **Lymphatic Vessels of the Face** are divided into two sets, *superficial* and *deep*.

The **superficial lymphatic vessels of the face** are more numerous than those of the head, and commence over its entire surface. Those from the frontal region accompany the frontal vessels; they then pass obliquely across the face, running

FIG. 395.—The superficial lymphatics and glands of the head, face, and neck.

with the facial vein, pass through the buccal glands on the surface of the Buccinator muscle, and join the submaxillary lymphatic glands. The latter receive the lymphatic vessels from the lips, and are often found enlarged in cases of malignant disease of those parts.

The **deep lymphatic vessels of the face** are derived from the pituitary membrane of the nose, the mucous membrane of the mouth and pharynx, and the contents of the temporal and orbital fossæ; they accompany the branches of the internal maxillary artery, and terminate in the internal maxillary and cervical lymphatic glands.

The **lymphatic vessels of the cranium** consist of two sets, the *meningeal* and *cerebral*. The *meningeal lymphatics* accompany the meningeal vessels, escape through foramina at the base of the skull, and join the deep cervical lymphatic glands. The *cerebral lymphatics* are described by Eshmann as being situated between the arachnoid and pia mater, as well as in the choroid plexuses of the

lateral ventricles; they accompany the trunks of the carotid and vertebral arteries, and probably pass through foramina at the base of the skull to terminate in the deep cervical glands. They have not at present been demonstrated in the dura mater or in the substance of the brain.

The **Lymphatic Glands of the Neck** are divided into two sets, *superficial* and *deep*.

The **superficial cervical glands** may be arranged in three sets: (1) The *submaxillary*, ten to fifteen in number, situated beneath the body of the lower

FIG. 396.—The deep lymphatics and glands of the neck and thorax.

jaw in the submaxillary triangle; (2) *suprahyoid*, situated in the middle line of the neck, between the anterior bellies of the two digastric muscles; and (3) *cervical*, placed in the course of the external jugular vein between the Platysma and deep fascia. They are most numerous at the root of the neck, in the triangular interval between the clavicle, the Sterno-mastoid, and the Trapezius, where they are continuous with the axillary glands. A few small glands are also found on the front and sides of the larynx.

The **deep cervical glands** (Fig. 396) are numerous and of large size; they form a chain along the sheath of the carotid artery and internal jugular vein, lying by the side of the pharynx, œsophagus, and trachea, and extending from the base of the skull to the thorax, where they communicate with the lymphatic glands in that cavity. They are subdivided into two sets: an *upper*, ten to twenty in number,

situated about the bifurcation of the common carotid and along the upper part of the internal jugular vein; and a *lower*, ten to fifteen in number, clustered around the lower part of the internal jugular vein, and extending outward into the supra-clavicular fossa, where they are continuous with the axillary glands. Internally, this set is continuous with the mediastinal glands.

The **superficial and deep cervical lymphatic vessels** are a continuation of those already described on the cranium and face. After traversing the glands in those regions, they pass through the chain of glands which lie along the sheath of the carotid vessels, being joined by the lymphatics from the pharynx, œsophagus, larynx, trachea, and thyroid gland. At the lower part of the neck, after receiving some lymphatics from the thorax, they unite into a single trunk, which terminates, on the left side, in the thoracic duct; on the right side, in the right lymphatic duct.

Surgical Anatomy.—The cervical glands are very frequently the seat of tuberculous trouble. This condition is most usually set up by some lesion in those parts from which they receive their lymph. This excites some inflammation, which subsequently takes on a tuberculous character. It is very desirable, therefore, for the surgeon, in dealing with these cases, to possess a knowledge of the relation of the respective groups of glands to the periphery. The following table is extracted from Mr. Treves's work on *Serofula and its Gland Diseases*:

Scalp.—Posterior part = suboccipital and mastoid glands. Frontal and parietal portions = parotid glands.

Lymphatic vessels from the scalp also enter the superficial cervical set of glands.

Skin of face and neck = submaxillary, parotid, and superficial cervical glands.

External ear = superficial cervical glands.

Lower lip = submaxillary and suprahyoid glands.

Buccal cavity = submaxillary and upper set of deep cervical glands.

Gums of lower jaw = submaxillary glands.

Tongue.—Anterior portion = suprahyoid and submaxillary glands. Posterior portion = upper set of deep cervical glands.

Tonsils and palate = upper set of deep cervical glands.

Pharynx.—Upper part = parotid and retro-pharyngeal glands. Lower part = upper set of deep cervical glands.

Larynx, orbit, and roof of mouth = upper set of deep cervical glands.

Nasal fossæ = retro-pharyngeal glands, upper set of deep cervical glands. Some lymphatic vessels from posterior part of the fossæ enter the parotid glands.

LYMPHATICS OF THE UPPER EXTREMITY.

The **Lymphatic Glands of the Upper Extremity** (Fig. 397) are divided into two sets, *superficial* and *deep*.

The **superficial lymphatic glands** are few and of small size. There are occasionally two or three in front of the elbow, and one or two above the internal condyle of the humerus, near the basilic vein.

The **deep lymphatic glands** are few in number, and are subdivided into those in the forearm, the arm, and the axilla. In the *forearm* a few small ones are occasionally found in the course of the radial and ulnar vessels. In the *arm* there is a chain of small glands along the inner side of the brachial artery. One, sometimes two, fairly constant glands are situated a little above and in front of the inner condyle of the humerus. In the *axilla* they are of large size, and usually ten or twelve in number. A chain of these glands surrounds the axillary vessels, imbedded in a quantity of loose areolar tissue; they receive the lymphatic vessels from the arm; others are dispersed in the areolar tissue of the axilla; the remainder are arranged in two series, a small chain running along the lower border of the Pectoralis major, receiving the lymphatics from the front of the chest and mamma; and others are placed along the lower margin of the posterior wall of the axilla, which receive the lymphatics from the integument of the back. Two or three subclavian lymphatic glands are placed immediately beneath the clavicle; it is through these that the axillary and deep cervical glands communicate with each other.

Surgical Anatomy.—In malignant diseases, tumors, or other affections implicating the upper part of the back and shoulder, the front of the chest and mamma, the upper part of the

front and side of the abdomen, or the hand, forearm, and arm, the axillary glands are liable to be found enlarged.

The lymphatic vessels of the upper extremity are divided into two sets, *superficial* and *deep*.

The **superficial lymphatic vessels of the upper extremity** commence on the fingers, two vessels running along either side of each finger, one on the palmar and the other on the dorsal surface. Those on the palmar surface form an arch in the

FIG. 397.—The superficial lymphatics and glands of the upper extremity.

palm of the hand, from which are derived two sets of vessels, which pass up the forearm, taking the course of the subcutaneous veins. The lymphatics from the dorsal surface of the fingers form a plexus on the back of the hand, and, winding around the inner and outer borders of the forearm, unite with those in front. Those from the inner border of the hand accompany the ulnar veins along the inner side of the forearm to the bend of the elbow, where they are joined by some lymphatics from the outer side of the forearm: they then follow the course of the basilic vein, communicate with the glands immediately above the elbow, and terminate in the axillary glands, joining with the deep lymphatics. The superficial lymphatics from

the outer and back part of the hand accompany the radial veins to the bend of the elbow. They are less numerous than the preceding. At the bend of the elbow the greater number join the basilic group; the rest ascend with the cephalic vein on the outer side of the arm, some crossing the upper part of the Biceps obliquely, to terminate in the axillary glands, whilst one or two accompany the cephalic vein in the cellular interval between the Pectoralis major and Deltoid, and enter the subclavian lymphatic glands.

The **deep lymphatic vessels of the upper extremity** accompany the deep blood-vessels. In the forearm they consist of four sets, corresponding with the radial, ulnar, and interosseous arteries; they pass through the glands occasionally found in the course of those vessels, and communicate at intervals with the superficial lymphatics. In their course upward some of them pass through the glands which lie upon the brachial artery; they then enter the axillary and subclavian glands, and at the root of the neck terminate on the left side in the thoracic duct, and on the right side in the right lymphatic duct.

LYMPHATICS OF THE LOWER EXTREMITY.

The **Lymphatic Glands of the Lower Extremity** are divided into two sets, *superficial* and *deep*. The superficial are confined to the inguinal region, forming the *superficial inguinal lymphatic glands*.

The **superficial inguinal lymphatic glands**, placed immediately beneath the integument, are of large size, and vary from eight to ten in number. They are divisible into two groups: an upper *oblique* set, disposed irregularly along Poupart's ligament, which receive the lymphatic vessels from the integument of the scrotum, penis, parietes of the abdomen, perineal and gluteal regions, and the mucous membrane of the urethra; and an inferior *vertical* set, which surround the saphenous opening in the fascia lata, a few being sometimes continued along the saphenous vein to a variable extent. This latter group receive the superficial lymphatic vessels from the lower extremity.

Surgical Anatomy.—These glands frequently become enlarged in diseases implicating the parts from which their lymphatics originate. Thus in malignant or syphilitic affections of the prepuce and penis, or of the labia majora in the female, in cancer seroti, in abscess in the perinaeum, or in any other diseases affecting the integument and superficial structures in those parts, or the subumbilical part of the abdominal wall or the gluteal region, the upper chain of glands is almost invariably enlarged, the lower chain being implicated in diseases affecting the lower limb.

The **deep lymphatic glands** are the anterior tibial, popliteal, deep inguinal, gluteal, and ischiatic.

The **anterior tibial gland** is not constant in its existence. It is generally found by the side of the anterior tibial artery, upon the interosseous membrane at the upper part of the leg. Occasionally, two glands are found in this situation.

The **popliteal glands**, four or five in number, are of small size; they surround the popliteal vessels, imbedded in the cellular tissue and fat of the popliteal space.

The **deep inguinal glands** are placed beneath the deep fascia around the femoral artery and vein. They are of small size, and communicate with the superficial inguinal glands through the saphenous opening.

The **gluteal and ischiatic glands** are placed, the former above, the latter below, the Piriformis muscle, resting on their corresponding vessels as they pass through the great sacro-sciatic foramen.

The **Lymphatic Vessels of the Lower Extremity**, like the veins, may be divided into two sets, *superficial* and *deep*.

The **superficial lymphatic vessels** are placed beneath the integument in the superficial fascia, and are divisible into two groups: an internal group, which follow the course of the internal saphenous vein; and an external group, which accompany the external saphenous. The *internal group*, the larger, commence on the inner side and dorsum of the foot; they pass, some in front and some behind

the inner ankle, run up the leg with the internal saphenous vein, pass with it behind the inner condyle of the femur, and accompany it to the groin, where they terminate in the group of superficial inguinal lymphatic glands which surround the saphenous opening. Some of the efferent vessels from these glands pierce the cribriform fascia and sheath of the femoral vessels, and terminate in a lymphatic gland contained in the femoral canal, thus establishing a communication between the lymphatics of the lower extremity and those of the trunk; others pierce the fascia lata and join the deep inguinal glands. The *external group* arise from the outer side of the foot, ascend in front of the leg, and, just below the knee, cross the tibia from without inward, to join the lymphatics on the inner side of the thigh. Others commence on the outer side of the foot, pass behind the outer malleolus, and accompany the external saphenous vein along the back of the leg, where they enter the popliteal glands.

The **deep lymphatic vessels of the lower extremity** are few in number and accompany the deep blood-vessels. In the leg they consist of three sets, the anterior tibial, peroneal, and posterior tibial, which accompany the corresponding blood-vessels, two or three to each artery; they ascend with the blood-vessels and enter the lymphatic glands in the popliteal space; the efferent vessels from these glands accompany the femoral vein and join the deep inguinal glands; from these, the vessels pass beneath Poupart's ligament and communicate with the chain of glands surrounding the external iliac vessels.

The deep lymphatic vessels of the gluteal and ischiatic regions follow the course of the blood-vessels, and join the gluteal and ischiatic glands at the great sacro-sciatic foramen.

LYMPHATICS OF THE PELVIS AND ABDOMEN.

The **Lymphatic Glands in the Pelvis** are the external iliac, the internal iliac, and the sacral. Those of the abdomen are the lumbar glands.

The **external iliac glands** form an uninterrupted chain round the external iliac vessels, three being placed round the commencement of the vessels just behind the

FIG. 398.—The superficial lymphatics and glands of the lower extremity.

crural arch. They communicate below with the deep inguinal lymphatic glands, and above with the lumbar glands.

The **internal iliac glands** surround the internal iliac vessels; they receive the lymphatic vessels corresponding to the branches of the internal iliac artery, and communicate with the lumbar glands.

The **sacral glands** occupy the sides of the anterior surface of the sacrum, some

FIG. 390.—The deep lymphatic vessels and glands of the abdomen and pelvis.

being situated in the meso-rectal fold. These and the internal iliac glands are affected in malignant disease of the bladder, rectum, or uterus.

The **lumbar glands** are very numerous; they are situated on the front of the lumbar vertebrae, surrounding the common iliac vessels, the aorta, and vena cava; they receive the lymphatic vessels from the lower extremities and pelvis, as well as from the testes and some of the abdominal viscera: the efferent vessels from these glands unite into a few large trunks, which, with the lacteals, form the commence-

ment of the thoracic duct. In addition to these there are a few small *lateral lumbar glands* which lie between the transverse processes of the vertebræ, behind the Psoas muscle, and receive lymphatics from the back. In some cases of malignant disease these glands become enormously enlarged, completely surrounding the aorta and vena cava, and occasionally greatly contracting the calibre of those vessels. In all cases of malignant disease of the testes and in malignant disease of the lower limb, before any operation is attempted, careful examination of the abdomen should be made, in order to ascertain if any enlargement exists; and if any should be detected, all operative measures should be avoided as fruitless.

The **Lymphatic Vessels of the Abdomen and Pelvis** may be divided into two sets, *superficial* and *deep*.

The **superficial lymphatic vessels of the walls of the abdomen and pelvis** follow the course of the superficial blood-vessels. Those derived from the integument of the lower part of the abdomen below the umbilicus follow the course of the superficial epigastric vessels and converge to the superior group of the superficial inguinal glands; a deeper set accompany the deep epigastric vessels, and communicate with the external iliac glands. The superficial lymphatics from the sides of the lumbar part of the abdominal wall wind round the crest of the ilium, accompanying the superficial circumflex iliac vessels, to join the superior group of the superficial inguinal glands; the greater number, however, run backward along with the ilio-lumbar and lumbar vessels, to join the lateral lumbar glands.

The **superficial lymphatic vessels of the gluteal region** turn horizontally round the outer side of the nates, and join the superficial inguinal glands.

The **superficial lymphatic vessels of the scrotum and perinæum** follow the course of the external pudic vessels, and terminate in the superficial inguinal glands.

The **superficial lymphatic vessels of the penis** occupy the sides and dorsum of the organ, the latter receiving the lymphatics from the skin covering the glans penis; they all converge to the upper chain of the superficial inguinal glands. The **deep lymphatic vessels of the penis** follow the course of the internal pudic vessels, and join the internal iliac glands.

In the female the lymphatic vessels of the mucous membrane of the labia, nymphæ, and clitoris terminate in the upper chain of the inguinal glands.

The **deep lymphatic vessels of the abdomen and pelvis** take the course of the principal blood-vessels. Those of the parietes of the pelvis, which accompany the gluteal, ischiatic, and obturator vessels, follow the course of the internal iliac artery, and ultimately join the lumbar lymphatics.

The efferent vessels from the inguinal glands enter the pelvis beneath Poupart's ligament, where they lie in close relation with the femoral vein; they then pass through the chain of glands surrounding the external iliac vessels, and finally terminate in the lumbar glands. They receive the deep epigastric and circumflex iliac lymphatics.

The **lymphatic vessels of the bladder** arise from the entire surface of the organ;¹ the greater number run beneath the peritoneum on its posterior surface, and, after passing through the lymphatic glands in that situation, join with the lymphatics from the prostate and vesiculæ seminales, and enter the internal iliac glands.

The **lymphatic vessels of the rectum** are of large size; after passing through some small glands that lie upon its outer wall and in the meso-rectum they pass to the sacral glands.

The **lymphatic vessels of the uterus** consist of two sets, *superficial* and *deep*, the former being placed beneath the peritoneum, the latter in the substance of the organ. The lymphatics of the cervix uteri, together with those from the vagina, enter the internal iliac and sacral glands; those from the body and fundus of the uterus pass outward in the broad ligaments, and, being joined by the lymphatics

¹ Curnow states that they are confined to the base of the organ.

from the ovaries, broad ligaments, and Fallopian tubes, ascend with the ovarian vessels to open into the lumbar glands. In the unimpregnated uterus they are small, but during gestation they become very greatly enlarged.

The **lymphatic vessels of the testicle** consist of two sets, *superficial* and *deep*: the former commence on the surface of the tunica vaginalis, the latter in the epididymis and body of the testis. They form several large trunks which ascend with the spermatic cord, and, accompanying the spermatic vessels into the abdomen, terminate into the lumbar glands; hence the enlargement of these glands in malignant disease of the testis.

The **lymphatic vessels of the kidney** arise on the surface, and also in the interior of the organ; they join at the hilum, and, after receiving the lymphatic vessels from the ureter and suprarenal capsules, open into the lumbar glands.

The **lymphatic vessels of the liver** are divisible into two sets, *superficial* and *deep*. The former arise in the subperitoneal areolar tissue over the entire surface of the organ. Those on the convex surface may be divided into four groups: 1. Those which pass from behind forward, consisting of three or four branches, which ascend in the longitudinal ligament and unite to form a single trunk, which passes up between the fibres of the Diaphragm, behind the ensiform cartilage, to enter the anterior mediastinal glands, and finally ascends to the root of the neck, to terminate in the right lymphatic duct. 2. Another group, which also incline from behind forward, are reflected over the anterior margin of the liver to its under surface, and from thence pass along the longitudinal fissure to the glands in the gastro-hepatic omentum. 3. A third group incline outward to the right lateral ligament, and, uniting into one or two large trunks, pierce the Diaphragm, and run along its upper surface to enter the anterior mediastinal glands, or, instead of entering the thorax, turn inward across the crus of the Diaphragm and open into the commencement of the thoracic duct. 4. The fourth group incline outward from the surface of the left lobe of the liver to the left lateral ligament, pierce the Diaphragm, and, passing forward, terminate in the glands in the anterior mediastinum.

The *superficial lymphatics on the under surface of the liver* are divided into three sets: 1. Those on the right side of the gall-bladder enter the lumbar glands. 2. Those surrounding the gall-bladder form a remarkable plexus; they accompany the hepatic vessels, and open into the glands in the gastro-hepatic omentum. 3. Those on the left of the gall-bladder pass to the œsophageal glands and to the glands which are situated along the lesser curvature of the stomach.

The *deep lymphatics* accompany the branches of the portal vein and the hepatic artery and duct through the substance of the liver; passing out at the transverse fissure, they enter the lymphatic glands along the lesser curvature of the stomach and behind the pancreas, or join with one of the lacteal vessels previous to its termination in the thoracic duct.

The **lymphatic glands of the stomach** are of small size; they are placed along the lesser and greater curvatures, some within the gastro-splenic omentum, whilst others surround the cardiac and pyloric orifices.

The **lymphatic vessels of the stomach** consist of two sets, *superficial* and *deep*, the former originating in the subserous, and the latter in the submucous, coat. They follow the course of the blood-vessels, and may consequently be arranged into three groups: The *first group* accompany the gastric vessels along the lesser curvature, receiving branches from both surfaces of the organ, and pass to the glands around the pylorus. The *second group* pass from the great end of the stomach, accompanying the vasa brevia, and enter the splenic lymphatic glands. The *third group* run along the greater curvature with the right gastro-epiploic vessels, and terminate at the root of the mesentery in one of the principal lacteal vessels.

The **lymphatic glands of the spleen** occupy the hilum. Its *lymphatic vessels* consist of two sets, *superficial* and *deep*: the former are placed beneath its peritoneal covering, the latter in the substance of the organ; they accompany the

blood-vessels, passing through a series of small glands, and, after receiving the lymphatics from the pancreas, ultimately pass into the thoracic duct.

THE LYMPHATIC SYSTEM OF THE INTESTINES.

The **lymphatic glands of the small intestine** are placed between the layers of the mesentery, occupying the meshes formed by the superior mesenteric vessels, and hence called *mesenteric glands*. They vary in number from a hundred to a hundred and fifty, and in size from that of a pea to that of a small almond. These glands are most numerous, and largest above, near the duodenum, and below, opposite the termination of the ileum in the colon. This latter group becomes enlarged and infiltrated with deposit in cases of fever accompanied with ulceration of the intestines.

The **lymphatic glands of the large intestine** are much less numerous than the mesenteric glands; they are situated along the vascular arches formed by the arteries previous to their distribution, and even sometimes upon the intestine itself. They are fewest in number along the transverse colon, where they form an uninterrupted chain with the mesenteric glands.

The **lymphatic vessels of the small intestine** are called *lacteals*, from the milk-white fluid they usually contain: they consist of two sets, superficial and deep, the former lie between the layers of the muscular coat and between the muscular and peritoneal coats, taking a longitudinal course along the outer side of the intestine; the latter occupy the submucous tissue, and course transversely round the intestine, accompanied by the branches of the mesenteric vessels; they pass between the layers of the mesentery, enter the mesenteric glands, and finally unite to form two or three large trunks which terminate in the thoracic duct.

The **lymphatic vessels of the large intestine** consist of two sets: those of the cæcum, ascending and transverse colon, which, after passing through their proper glands, enter the mesenteric glands; and those of the descending colon, sigmoid flexure, and rectum, which pass to the lumbar glands.

THE LYMPHATICS OF THE THORAX.

The **Lymphatic Glands of the Thoracic Wall** are the intercostal, internal mammary, anterior mediastinal, and posterior mediastinal.

The **intercostal glands** are small, irregular in number, and situated on each side of the spine, near the costo-vertebral articulations, some being placed between the two planes of intercostal muscles.

The **internal mammary glands** are placed at the anterior extremity of each intercostal space, by the side of the internal mammary vessels.

The **anterior mediastinal glands** are placed in the loose areolar tissue of the anterior mediastinum, some lying upon the Diaphragm in front of the pericardium, and others round the great vessels at the base of the heart.

The **posterior mediastinal glands** are situated in the areolar tissue in the posterior mediastinum, forming a continuous chain by the side of the aorta and œsophagus; they communicate on each side with the intercostal, below with the lumbar, and above with the deep cervical glands.

The **Superficial Lymphatic Vessels of the Front of the Thorax** run across the great Pectoral muscle, and those on the back part of this cavity lie upon the Trapezius and Latissimus dorsi; they all converge to the axillary glands. The lymphatics from the greater part of the mammary gland pass outward to the lower border of the Pectoralis major muscle, where they enter a chain of small glands situated in the axillary space along the lower border of its anterior boundary. Some few lymphatics from the inner side of the mammary gland pass through the intercostal spaces to reach the anterior mediastinal glands.

The **Deep Lymphatic Vessels of the Thoracic Wall** are the intercostal, internal mammary, and diaphragmatic.

The **intercostal lymphatic vessels** follow the course of the intercostal vessels,

receiving lymphatics from the intercostal muscles and pleura; they pass backward to the spine, and unite with lymphatics from the back part of the thorax and spinal canal. After traversing the intercostal glands, they pass down the spine and terminate in the thoracic duct.

The **internal mammary lymphatic vessels** follow the course of the internal mammary vessels; they commence in the muscles of the abdomen above the umbilicus, communicating with the epigastric lymphatics, ascend between the fibres of the Diaphragm at its attachment to the ensiform appendix, and in their course behind the costal cartilages are joined by the intercostal lymphatics; they terminate on the right side in the right lymphatic duct, on the left side in the thoracic duct.

The **lymphatic vessels of the Diaphragm** follow the course of their corresponding vessels, and terminate, some in front in the anterior mediastinal and internal mammary glands, some behind, in the intercostal and posterior mediastinal lymphatics.

The **Lymphatic Glands of the Viscera** are the bronchial glands.

The **bronchial glands** are situated round the bifurcation of the trachea and roots of the lungs. They are ten or twelve in number, the largest being placed opposite the bifurcation of the trachea, the smallest round the bronchi and their primary divisions for some little distance within the substance of the lungs. In infancy they present the same appearance as lymphatic glands in other situations; in the adult they assume a brownish tinge, and in old age a deep black color. Occasionally they become sufficiently enlarged to compress and narrow the canal of the bronchi, and they are often the seat of tubercle or cretaceous deposits.

The **lymphatic vessels of the lung** consist of two sets, *superficial* and *deep*: the former are placed beneath the pleura, forming a minute plexus which covers the outer surface of the lung; the latter accompany the blood-vessels and run along the bronchi: they both terminate at the root of the lungs in the bronchial glands. The efferent vessels from these glands, two or three in number, ascend upon the trachea to the root of the neck, traverse the tracheal and œsophageal glands, and terminate on the left side in the thoracic duct and on the right side in the right lymphatic duct.

The **cardiac lymphatic vessels** consist of two sets, *superficial* and *deep*: the former arise in the subserous areolar tissue of the surface, and the latter in the deeper tissues of the heart. They follow the course of the coronary vessels: those of the right side unite into a trunk at the root of the aorta, which, ascending across the arch of that vessel, passes backward to the trachea, upon which it ascends, to terminate at the root of the neck in the right lymphatic duct. Those of the left side unite into a single vessel at the base of the heart, which, passing along the pulmonary artery and traversing some glands at the root of the aorta, ascends on the trachea to terminate in the thoracic duct.

The **thymic lymphatic vessels** arise from the under surface of the thymus gland, and terminate on each side in the internal jugular veins.

The **thyroid lymphatic vessels** arise from either lateral lobe of this organ: they converge to form a short trunk, which terminates on the right side in the right lymphatic duct, on the left side in the thoracic duct.

The **lymphatic vessels of the œsophagus** form a plexus round that tube, traverse the glands in the posterior mediastinum, and, after communicating with the pulmonary lymphatic vessels near the roots of the lungs, terminate in the thoracic duct.

THE NERVOUS SYSTEM.

THE Nervous System is composed—1. Of a series of large centres of nerve-matter, called, collectively, the *cerebro-spinal centre* or *axis*. 2. Of smaller centres, termed *ganglia*. 3. Of *nerves*, connected either with the cerebro-spinal axis or the ganglia. And 4. Of certain modifications of the peripheral terminations of the nerves, forming the organs of the external senses.

The **Cerebro-spinal Centre** consists of two parts, the spinal cord and the encephalon; the latter may be subdivided into the cerebrum, the cerebellum, the pons Varolii, and the medulla oblongata.

THE SPINAL CORD AND ITS MEMBRANES.

Dissection.—To dissect the cord and its membranes it will be necessary to lay open the whole length of the spinal canal. For this purpose the muscles must be separated from the vertebral grooves, so as to expose the spinous processes and laminae of the vertebrae; and the latter must be sawn through on each side, close to the roots of the transverse processes, from the third or fourth cervical vertebra above to the sacrum below. The vertebral arches having been displaced by means of a chisel and the separate fragments removed, the dura mater will be exposed, covered by a plexus of veins and a quantity of loose areolar tissue, often infiltrated with serous fluid. The arches of the upper vertebrae are best divided by means of a strong pair of cutting bone-forceps.

MEMBRANES OF THE CORD.

The membranes which envelop the spinal cord are three in number. The most external is the *dura mater*, a strong fibrous membrane which forms a loose sheath around the cord. The most internal is the *pia mater*, a cellulo-vascular membrane which closely invests the entire surface of the cord. Between the two is the *arachnoid membrane*, a non-vascular membrane which envelops the cord and is connected to the pia mater by slender filaments of connective tissue.

The **Dura Mater** of the cord, continuous with that which invests the brain, is a loose sheath which surrounds the cord, and is separated from the bony walls of the spinal canal by a quantity of loose areolar tissue and a plexus of veins. It is attached to the circumference of the foramen magnum and to the posterior common ligament, especially at the lower end of the spinal canal, by fibrous slips, and extends below as far as the third piece of the sacrum; but beyond this point it is impervious, being continued in the form of a slender cord to the back of the coccyx, where it blends with the periosteum. This sheath is much larger than is necessary for its contents, and its size is greater in the cervical and lumbar regions than in the dorsal. Its inner surface is smooth. On each side may be seen the double openings which transmit the two roots of the corresponding spinal nerve, the fibrous layer of the dura mater being continued in the form of a tubular prolongation on them as they pass through these apertures. These prolongations of the dura mater are short in the upper part of the spine, but become gradually longer below, forming a number of tubes of fibrous membrane which enclose the sacral nerves and are contained in the spinal canal.

The chief peculiarities of the dura mater of the cord, as compared with that investing the brain, are the following:

The dura mater of the cord is not adherent to the bones of the spinal canal, which have an independent periosteum.

It does not send partitions into the fissures of the cord, as in the brain.

Its fibrous laminae do not separate to form venous sinuses, as in the brain.

Structure.—The dura mater consists of white fibrous and elastic tissue arranged in bands or lamellae, which, for the most part, are parallel with one another. Its internal surface is covered by a layer of endothelial cells which gives this surface its smooth appearance. It is sparingly supplied with vessels, and some few nerves have been traced into it.

FIG. 400.—The spinal cord and its membranes.

The **Arachnoid** is exposed by slitting up the dura mater and reflecting that membrane to either side (Fig. 400). It is a thin, delicate, tubular membrane which invests the surface of the cord, and is connected to the pia mater by slender filaments of connective tissue. Above, it is continuous with the cerebral arachnoid; on each side it is continued on the various nerves, so as to form a sheath for them as they pass outward to the intervertebral foramina. The outer surface of the arachnoid is in contact with the inner surface of the dura mater, and the two are, here and there, connected together by isolated connective-tissue trabeculae, especially on the posterior surface of the cord. For the most part, however, the membranes are not connected together, and the interval between them is named the *subdural space*. The inner surface of the arachnoid is separated from the pia mater by a considerable interval, which is called the *subarachnoidean space*. The space is the largest at the lower part of the spinal canal, and encloses the mass of nerves which form the cauda

equina. Superiorly it is continuous with the cranial subarachnoid space, and communicates with the general ventricular cavity of the brain by means of an opening in the pia mater at the inferior boundary of the fourth ventricle (*foramen of Majendie*). It contains an abundant serous secretion, the *cerebro-spinal fluid*.

This secretion is sufficient in amount to expand the arachnoid membrane, so as to completely fill up the whole of the space included in the dura mater. The subarachnoidean space is occupied by trabeculae of delicate connective tissue, connecting the pia mater on the one hand with the arachnoid membrane on the other. This is named *subarachnoid tissue*. In addition to this it is partially subdivided by a longitudinal membranous partition, which serves to connect the arachnoid with the pia mater, opposite the posterior median fissure. This partition is in-

FIG. 401.—Transverse section of the spinal cord and its membranes.

complete and cribriform in structure, consisting of bundles of white fibrous tissue interlacing with each other. This space is to be regarded as, in reality, a great lymph-space, from which the lymph carried to it by the perivascular lymph-sheath (see page 87) is conveyed back into the circulation.

Structure.—The arachnoid is a delicate membrane made up of closely arranged interlacing bundles of connective tissue in several layers.

The **Pia Mater** of the cord is exposed on the removal of the arachnoid (Fig. 400). It covers the entire surface of the cord, to which it is very intimately adherent, forming its neurilemma, and sending a process downward into its anterior fissure. It also forms a sheath for each of the filaments of the spinal nerves, and invests the nerves themselves. A longitudinal fibrous band extends along the middle line on its anterior surface, called by Haller the *linea splendens*; and a somewhat similar band, the *ligamentum denticulatum*, is situated on each side. At the point where the cord terminates the pia mater becomes contracted, and is con-

tinued down as a long, slender filament (*filum terminale*), which descends through the centre of the mass of nerves forming the cauda equina, and is blended with the impervious sheath of dura mater on a level with the third sacral vertebra. It assists in maintaining the cord in its position during the movements of the trunk, and is from this circumstance called the *central ligament* of the spinal cord. It contains a little gray nervous substance, which may be traced for some distance into its upper part, and is accompanied by a small artery and vein. At the upper part of the cord the pia mater presents a grayish, mottled tint, which is owing to yellow or brown pigment-cells scattered among the elastic fibres.

Structure.—The pia mater of the cord is less vascular in structure, but thicker and denser, than the pia mater of the brain, with which it is continuous. It consists of two layers: an outer composed of bundles of connective-tissue fibres, arranged for the most part longitudinally; and an inner, consisting of stiff bundles of the same tissue, which present peculiar angular bends, and is covered on both surfaces by a layer of endothelium. Between the two layers are a number of cleftlike lymphatic spaces which communicate with the subarachnoid cavity, and a number of blood-vessels which are enclosed in a perivascular sheath, derived from the inner layer of the pia mater, into which the lymphatic spaces open. It is also supplied with nerves, which are derived from the sympathetic.

The **Ligamentum Denticulatum** (Fig. 400) is a narrow fibrous band, situated on each side of the spinal cord, throughout its entire length, and separating the anterior from the posterior roots of the spinal nerves. It has received its name from the serrated appearance which it presents. Its inner border is continuous with the pia mater at the side of the cord. Its outer border presents a series of triangular, dentated serrations, the points of which are fixed at intervals to the dura mater. These serrations are twenty-one in number on each side, the first being attached to the dura mater, opposite the margin of the foramen magnum between the vertebral artery and the hypoglossal nerve, and the last near the lower end of the cord. Its use is to support the cord in the fluid by which it is surrounded.

THE SPINAL CORD.

The **Spinal Cord** (*medulla spinalis*) is the cylindrical, elongated part of the cerebro-spinal axis which is contained in the vertebral canal. Its length is usually about seventeen or eighteen inches, and its weight, when divested of its membranes and nerves, about one ounce and a half, its proportion to the encephalon being about 1 to 33. It does not nearly fill the canal in which it is contained, its investing membranes being separated from the surrounding walls by areolar tissue and a plexus of veins. It occupies, in the adult, the upper two-thirds of the vertebral canal, extending from the upper border of the atlas to the lower border of the body of the first lumbar vertebra, where it terminates in a slender filament of gray substance, which is continued for some distance into the *filum terminale*. In the fœtus, before the third month, it extends to the bottom of the sacral canal, but after this period it gradually recedes from below, as the growth of the bones composing the canal is more rapid in proportion than that of the cord, so that in the child at birth the cord extends as far as the third lumbar vertebra. Its position varies also according to the degree of curvature of the spinal column, being raised somewhat in flexion of the spine. On examining its surface it presents a difference in its diameter in different parts, being marked by two enlargements, an upper or cervical, and a lower or lumbar. The cervical enlargement, which is the larger, extends from about the third cervical to the first or second dorsal vertebra: its greatest diameter is in the transverse direction, and it corresponds with the origin of the nerves which supply the upper extremities. The lower, or lumbar, enlargement is situated opposite the last two or three dorsal vertebræ, its greatest diameter being from before back-

ward. It corresponds with the origin of the nerves which supply the lower extremities. In form the spinal cord is a flattened cylinder.

Fissures.—It presents on its anterior surface, along the middle line, a longitudinal fissure, the *anterior median fissure*, and on its posterior surface another fissure, which also extends along the entire length of the cord, the *posterior median fissure*. These fissures penetrate through the greater part of the thickness of the cord, and incompletely divide the cord into two symmetrical halves, united in the middle line by a transverse band of nervous substance, the *commissure*.

FIG. 402.—Spinal cord. Side view. Plan of the fissures and columns.

The **Anterior Median Fissure** is wider, but of less depth, than the posterior, extending into the cord for about one-third of its thickness, and is deepest at the lower part of the cord. It contains a prolongation from the pia mater, and its floor is formed by the *anterior white commissure*, which is perforated by numerous blood-vessels passing to the centre of the cord.

The **Posterior Median Fissure** is not an actual fissure, as the space between the lateral halves of the posterior part of the cord is crossed by connective tissue and numerous blood-vessels, so that no actual hiatus exists, and there is consequently no prolongation of the pia mater into it. It extends into the cord to about one half its depth, and its floor is formed by the *posterior gray commissure*.

Lateral Fissures.—On each side of the anterior median fissure a linear series of foramina may be observed, indicating the points where the anterior roots of the spinal nerves emerge from the cord. This is called, by some anatomists, the *antero-lateral fissure* of the cord, although no actual fissure exists in this situation. And on each side of the posterior median fissure, along the line of attachment of the posterior roots of the nerves, a delicate fissure may be seen, leading down to the gray matter which approaches the surface in this situation; this is called the *postero-lateral fissure* of the spinal cord. On the posterior surface of the spinal cord, between the posterior median fissure and the postero-lateral fissure on each side, is a slight longitudinal furrow marking off two slender tracts, the *posterior median columns*. These are most distinct in the cervical region, but are stated by Foville to exist throughout the whole length of the cord.

Columns of the Cord.—Each half of the spinal cord is thus divided into four columns: an anterior column, a lateral column, a posterior column, and a posterior median column.

The *anterior column* includes all the portion of the cord between the anterior median fissure and the line from which the anterior roots of the nerves arise. It is continuous with the pyramid of the medulla oblongata.

The *lateral column*, the largest segment of the cord, includes all the portion between the line of origin of the anterior roots of the spinal nerves and the postero-lateral fissure. By some anatomists the anterior and lateral columns are included together under the name of the *antero-lateral column*, which forms rather more than two-thirds of the entire circumference of the cord.

The *posterior column* is situated between the posterior median and postero-lateral fissures.

The *posterior median column* is that narrow segment of the cord which is seen on each side of the posterior median fissure, usually included with the preceding as the posterior column.

Structure of the Cord.—If a transverse section of the spinal cord be made, it will be seen to consist of white and gray nervous substance. The white matter is situated externally, and constitutes the greater part. The gray substance occupies the centre, and is so arranged as to present on the surface of the section two crescentic masses, placed one in each lateral half of the cord, united together by a

transverse band of gray matter, the *gray commissure*. Each crescentic mass has an anterior and posterior horn. The posterior horn is long and narrow, and approaches the surface of the postero-lateral fissure, near which it presents a slight enlargement, the *caput cornu*: from this it tapers to form the *apex cornu*, which at the surface of the cord becomes continuous with the fibres of the posterior roots of the spinal nerves. The anterior horn is short and thick, and does not quite reach the surface, but extends toward the point of attachment of the anterior roots of the nerves. Its margin presents a dentate or stellate appearance. Owing to the projections toward the surface of the anterior and posterior horns of the gray matter, each half of the cord is divided, more or less completely, into three columns, anterior, middle, and posterior, the anterior and middle being joined to form the antero-lateral column, as the anterior horn does not quite reach the surface.

FIG. 403.—Transverse sections of the cord.

FIG. 404.—From a transverse section through the spinal cord of a calf. Magnified about 180 diameters, showing part of the central canal and the tissue immediately around it—viz. the central gray nucleus. (Klein and Noble Smith.) The canal is lined with epithelium, composed of ciliated, more or less conical, cells; in most instances a filamentous process passes from the cell into the tissue underneath. This tissue contains, in a hyaline matrix, a network of fibrils: most of these run horizontally, others have a longitudinal course, and appear therefore here cut transversely—i. e. as small dots. The nuclei correspond to the cells of the neuroglia, the cell-substance not being shown. Both the nuclei of the neuroglia-cells and those of the epithelium contain three or more large disk-shaped particles.

The **commissure of the spinal cord** is composed of white and gray fibres, hence called the white and gray commissures. The *white commissure* is formed of fibres, which pass horizontally between the gray matter of the anterior horn of one side and the anterior white column of the opposite side.

The *gray commissure*, which connects the two crescentic masses of gray matter, is separated from the bottom of the anterior median fissure by the anterior white commissure. It consists of transverse fibres, with a considerable quantity of neuroglia between them. The fibres when they reach the lateral crescents diverge: some pass backward to the posterior roots; others spread out, at various angles, into the cervix cornu.

Running through the gray commissure of the whole length of the cord is a minute canal, which is barely visible to the naked eye in the human cord, but is proportionally larger in some of the lower vertebrata. It is called the *central canal*, and opens above into the fourth ventricle, and terminates below in a somewhat dilated extremity. It is lined in the fœtus by columnar ciliated epithelium, but in the adult the cilia have disappeared, and the canal is filled with their remains. The cells are supported on a layer of neuroglia, which is sometimes called the *substantia gelatinosa centralis*.

The mode of arrangement of the gray matter, and its amount in proportion to the white, vary in different parts of the cord. Thus, the posterior horns are long and narrow in the cervical region; short and narrower in the dorsal; short, but wider, in the lumbar region. In the cervical region the crescentic portions are small, and the white matter more abundant than in any other region of the cord. In the dorsal region the gray matter is least developed, the white matter being also small in quantity. In the lumbar region the gray matter is more abundant than in any other region of the cord. Toward the lower end of the cord the white matter gradually ceases. The crescentic portions of the gray matter soon blend into a single mass, which forms the only constituent of the extreme point of the cord.

Minute Anatomy of the Cord.—The cord consists of an outer part, composed of medullated nerve-fibres, which is the *white substance*; and of a central part, the *gray matter*, both supported in a peculiar kind of connective tissue, called *neuroglia*.

The *neuroglia* consists of a homogeneous transparent matrix, of a network of very delicate fibrillæ, and of small stellate or branched cells, the *neuroglia-cells*.

In addition to forming a ground substance, in which the nerve-fibres, nerve-

FIG. 405.—Transverse section through the cervical portion of the spinal cord of the calf. Magnified 40 diameters. (Klein and Noble Smith.)

cells, and blood-vessels are imbedded, a considerable accumulation of neuroglia takes place in three situations—(1) on the surface of the cord, beneath the pia mater; (2) around the central canal; and (3) in the posterior part of the posterior horn, forming the *substantia cinerea gelatinosa*.

The **white substance of the cord** consists of medullated nerve-fibres, with blood-vessels and neuroglia. On transverse section of the white substance of the cord a very striking object is presented. It is seen to be studded all over with minute dots, surrounded by a white area, and this again by a dark circle (Fig. 409). This is due to the longitudinal medullated fibres seen on section. The dot is the axis-cylinder, the white area the substance of Schwann, and the dark circle the tubular membrane of the fibres, which seems to consist of several laminæ. Externally, the neuroglia is seen to form a delicate connective sheath round the outer surface of the cord immediately beneath the pia mater, from which numerous

septa pass in to separate the respective bundles of fibres and extend between the individual nerve-fibres, acting as a supporting medium in which they are imbedded. Thus it will be seen that the greater bulk of the white matter of the cord is made up of longitudinal medullated fibres, which are arranged in groups forming the anterior, lateral, and posterior columns.

There are, however, also oblique and transverse fibres in the white substance. These are principally found (1) at the bottom of the anterior median fissure, forming the white commissure, the fibres passing from the gray matter of the anterior horn on one side to the white matter of the anterior column of the opposite side; (2) horizontal or oblique fibres passing from the roots of the nerves into the gray matter; and (3) fibres leaving the gray matter, and pursuing a longer or shorter

FIG. 406.—Columns of the cord.

FIG. 407.—Transverse section of the gray substance of the spinal cord, near the middle of the dorsal region. Magnified 13 diameters.

horizontal course between the bundles of longitudinal fibres, with which many of them are continuous.

The investigation of pathological lesions has shown that the white matter of the cord consists of certain columns or tracts of fibres, for it has been found that separate lesions are strictly limited to certain well-determined parts of the organ without involving neighboring regions. That these parts or fasciculi correspond to so many distinct anatomical systems, each endowed with special functions, seems abundantly proved by the researches of Flechsig and others on the development of the cord during the later periods of utero-gestation and in the newly-born infant. Thus, on either side of the anterior median fissure a portion of the anterior column is divided off as the *Direct pyramidal fasciculus* (fasciculus of Türek), which can be traced to be continuous with the non-decussating fibres of the pyramid of the medulla. The remainder of the anterior column of the cord forms the *fundamental fasciculus*, which is continued into the deeper part of the medulla. The lateral column of the cord is divided into four tracts, the anterior division of which is called the *anterior radicular zone*, the peripheral portion of the posterior part the *cerebellar column*, and the internal part, next the gray substance, is termed the *mixed lateral column*; whilst an intermediate portion, between these last two, is the *crossed pyramidal fasciculus*, its fibres when traced upward forming the decussating portion of the pyramid of the medulla oblongata. The other three portions of the lateral column can be traced into the *lateral tract* of the medulla, the peripheral fibres, or those forming the cerebellar column, passing through it to the cerebellum.

The posterior column of the cord is divided into two: the portion which lies next the posterior median fissure is called the *column of Goll* (posterior median),

and if traced upward is found to be continuous with the fasciculus gracilis of the medulla. The remainder of the posterior column is called the *cuneate fasciculus*, or *Burdach's column* (posterior external), and is prolonged into the medulla under the same name.

The **gray substance of the cord** occupies its central part in the shape of two crescentic horns, joined together by a commissure. Each of these crescents has an anterior and posterior cornu.

The *posterior horn* consists of two parts—the *caput cornu*, or expanded extremity of the horn (Fig. 408), round which is a lighter space or lamina of

FIG. 408.—Transverse section of the gray substance of the spinal cord through the middle of the lumbar enlargement. On the left side of the figure groups of large cells are seen; on the right side, the course of the fibres is shown without the cells. Magnified 13 diameters.

gelatinous substance; and the *cervix cornu*, or narrower portion, which connects it with the rest of the gray substance.

The gelatinous substance is a peculiar accumulation of neuroglia (Klein), and has been named by Rolando the *substantia cinerea gelatinosa*.

The *anterior horn of the gray substance* in the cervical and lumbar swellings, where it gives origin to the nerves of the extremities, is much larger than in any other region, and contains several distinct groups of large and variously shaped cells.

In addition to this, in certain parts of the cord other horns or projections of the gray matter may be seen on transverse section. One of these, the *lateral horn*, is found projecting outward from the lateral region of the gray matter on a level with the gray commissure in the cervical and upper part of the dorsal region of the cord; and a second, *Clarke's vesicular column*, is found on the inner side of the posterior horn near the gray commissure, in the upper cervical or dorsal regions or at the point of exit of the lower lumbar nerves.

The gray commissure is situated behind the white commissure, which separates it from the bottom of the anterior median fissure.

The **gray substance of the cord** consists of—(1) nerve-fibres of variable but smaller average diameter than those of the columns; (2) nerve-cells of various shapes and sizes, with from two to eight processes; (3) blood-vessels and connective tissue.

The *nerve-fibres* of the gray matter of the posterior horn are for the most part composed of a minute and dense network of minute fibrils, which is termed "Gerlach's nerve-network," intermingled with nerves of a larger size. This network is continuous with the medullated fibres of the posterior nerve-roots on the one hand (Dieters), and with the branched processes of the ganglion-cells on the other (Gerlach), so that the ganglion-cells are connected with the medullated fibres of the posterior nerve-roots only indirectly through the nerve-network. The arrangement of the fibres in the anterior horn of the gray matter appears to be somewhat different; here the medullated fibres of the anterior nerve-roots are directly continuous with some of the processes of the ganglion-cells, others of the processes of the ganglion-cells communicating with Gerlach's nerve-network.

FIG. 409.—Longitudinal section of the white and gray substance of the spinal cord, through the middle of the lumbar enlargement. Magnified 14 diameters.

FIG. 410.—Transverse section through the white matter of the spinal cord of a calf. Magnified about 300 diameters. (Klein and Noble Smith.) In the upper part are shown two isolated flattened nucleated cells of the neuroglia, under a somewhat higher power than the rest. In the bulk of the figure the nerve-fibres are seen in transverse section. They are of different sizes, and possess a laminated medullary sheath surrounding the axis-cylinder, which was deeply stained in the preparation, and is here represented by a black dot. The nerve-fibres are imbedded in the neuroglia. This contains, in a matrix which appears sometimes granular, sometimes homogeneous, numerous elastic fibrils, seen here in transverse section as minute dots, on account of their having a course parallel to the long axis of the cord. Amongst the neuroglia are also seen two branched connective-tissue cells—neuroglia-cells.

The *nerve-cells* of the gray matter are of two kinds, large branched nerve-vesicles which are collected into groups, and small round cells which resemble free nuclei and are found scattered throughout the whole of the gray matter.

In the anterior horn is a constant group, situated at the anterior part of the cornu, and sometimes termed the *vesicular column of the anterior cornu*. It consists of two groups of cells: one mesial, near the anterior column; the other lateral, near the lateral column. At the base of the posterior horn on its inner side, and joining the gray commissure, is a group of nerve-cells, which give rise to the projection mentioned above as being seen on transverse section in the upper part of the cord, which is called Clarke's posterior vesicular column.

At the junction of the anterior and posterior cornu, in the outer portion of the gray matter, is a third group of cells, the *tractus intermedio-lateralis*. In certain regions of the cord these cells extend in amongst the fibres of the white matter of the lateral column, and give rise to the lateral horn. In addition to these groups a few large scattered cells are found in the posterior horn, extending into the substantia cinerea gelatinosa.

THE BRAIN AND ITS MEMBRANES.

Dissection.—To examine the brain with its membranes the skull-cap must be removed. In order to effect this, saw through the external table, the section commencing, in front, about an inch above the margin of the orbit, and extending, behind, to a level with the occipital protuberance. Then break the internal table with the chisel and hammer, to avoid injuring the investing membranes or brain; loosen and forcibly detach the skull-cap, when the dura mater will be exposed. The adhesion between the bone and the dura mater is very intimate, and much more so in the young subject than in the adult.

MEMBRANES OF THE BRAIN.

The membranes of the brain are the dura mater, arachnoid membrane, and pia mater.

The Dura Mater.

The **Dura Mater** is a thick and dense inelastic fibrous membrane which lines the interior of the skull. Its outer surface is rough and fibrillated, and adheres closely to the inner surface of the bones, forming their internal periosteum, this adhesion being most marked opposite the sutures and at the base of the skull. Its inner surface is smooth and lined by a layer of endothelial cells. It sends three processes inward, into the cavity of the skull, for the support and protection of the different parts of the brain, and is prolonged to the outer surface of the skull through the various foramina which exist at the base, and thus becomes continuous with the pericranium; its fibrous layer forms sheaths for the nerves which pass through these apertures. At the base of the skull it sends a fibrous prolongation into the foramen cæcum; it sends a series of tubular prolongations round the filaments of the olfactory nerves as they pass through the cribriform plate, and also round the nasal nerve as it passes through the nasal slit; a prolongation is also continued through the sphenoidal fissure into the orbit, and another is continued into the same cavity through the optic foramen, forming a sheath for the optic nerve, which is continued as far as the eyeball. In the posterior fossa it sends a process down the internal auditory meatus, ensheathing the facial and auditory nerves; another through the jugular foramen, forming a sheath for the structures which pass through this opening; and a third through the anterior condyloid foramen. Around the margin of the foramen magnum it is closely adherent to the bone, and is continuous with the dura mater lining the spinal canal. In certain situations, as already mentioned (page 652), the fibrous layers of this membrane separate, to form sinuses for the passage of venous blood. Upon the outer surface of the dura mater, in the situation of the longitudinal sinus, may be seen numerous small whitish bodies, the *glandulae Pacchioni*.

Structure.—The dura mater consists of white fibrous and elastic tissues arranged in flattened laminae, which are divisible into two layers, the fibres of the two layers intersecting each other obliquely. A layer of nucleated endothelial cells, similar to those found on serous membranes, lines its inner surface; these were formerly regarded as belonging to the arachnoid membrane.

Its *arteries* are very numerous, but are chiefly distributed to the bones. Those found in the anterior fossa are the anterior meningeal branches of the anterior and posterior ethmoidal and internal carotid, and a branch from the middle meningeal. In the middle fossa are the middle and small meningeal branches of the internal maxillary, a branch from the ascending pharyngeal, which enters the skull through the foramen lacerum medium basis cranii, branches from the internal carotid, and a recurrent branch from the lachrymal. In the posterior fossa are meningeal branches from the occipital, one of which enters the skull through the jugular foramen, and the other through the mastoid foramen; the posterior meningeal, from the vertebral; occasionally meningeal branches from the ascending pharyngeal, which enter the skull, one at the jugular foramen, the other at the anterior condyloid foramen, and a branch from the middle meningeal.

The *veins*, which return the blood from the dura mater, and partly from the bones, anastomose with the diploic veins. These vessels terminate in the various

sinuses, with the exception of two which accompany the middle meningeal artery, and pass out of the skull at the foramen spinosum to join the internal maxillary vein.

The *nerves* of the dura mater are, the recurrent branch of the fourth and filaments from the Gasserian ganglion, from the ophthalmic and hypoglossal nerves, and from the sympathetic.

The so-called *glandulæ Pacchioni* are numerous small whitish granulations, usually collected into clusters of variable size, which are found in the following situations: 1. Upon the outer surface of the dura mater, in the vicinity of the superior longitudinal sinus, being received into little depressions on the inner surface of the calvarium. 2. On the inner surface of the dura mater. 3. In the superior longitudinal sinus. 4. On the pia mater, near the margin of the hemispheres.

These bodies are not glandular in structure, but simply enlarged normal villi of the arachnoid. In their growth they perforate the dura mater, and are thus found on its outer surface, and when of large size they cause absorption of the bone, and come to be lodged in pits or depressions on the inner table of the skull. The manner in which they perforate the dura mater is as follows: At an early period of their growth they project through minute holes in the inner layer of the dura mater, which open into large venous spaces situated in the tissues of the membrane on either side of the longitudinal sinus and communicating with it. In their onward growth the villi push the outer layer of the dura mater before them, and this forms over them a delicate membranous sheath. In structure they consist of trabeculæ of connective tissue covered over by a layer of endothelium. The spongy tissue of which they are composed is continuous with the trabecular tissue of the subarachnoid space.

These bodies are not found in infancy, and very rarely until the third year. They are usually found after the seventh year, and from this period they increase in number as age advances. Occasionally they are wanting.

Processes of the Dura Mater.—The processes of the dura mater, sent inward into the cavity of the skull, are three in number: the *falx cerebri*, the *tentorium cerebelli*, and the *falx cerebelli*.

The *falx cerebri*, so named from its sickle-like form, is a strong arched process of the dura mater, which descends vertically in the longitudinal fissure between the two hemispheres of the brain. It is narrow in front, where it is attached to the crista galli of the ethmoid bone, and broad behind, where it is connected with the upper surface of the tentorium. Its upper margin is convex, and attached to the inner surface of the skull as far back as the internal occipital protuberance. In this situation it is broad, and contains the superior longitudinal sinus. Its lower margin is free, concave, and presents a sharp curved edge, which contains the inferior longitudinal sinus.

The *tentorium cerebelli* is an arched lamina of dura mater, elevated in the middle and inclining downward toward the circumference. It covers the upper surface of the cerebellum, and supports the occipital lobes of the brain, and prevents them pressing upon the cerebellum. It is attached, behind, by its convex border to the transverse ridges upon the inner surface of the occipital bone, and there encloses the lateral sinuses; in front, to the superior margin of the petrous portion of the temporal bone, enclosing the superior petrosal sinuses; and at the apex of this bone the free or internal border and the attached or external border meet, and, forming two processes, cross one another and are continued forward, to be attached to the anterior and posterior clinoid processes respectively. Along the middle line of its upper surface the posterior border of the *falx cerebri* is attached, the straight sinus being placed at their point of junction. Its anterior border is free and concave, and presents a large oval opening for the transmission of the *crura cerebri*.

The *falx cerebelli* is a small triangular process of dura mater received into the indentation between the two lateral lobes of the cerebellum behind. Its base is

attached, above, to the under and back part of the tentorium; its posterior margin, to the lower division of the vertical crest on the inner surface of the occipital bone. As it descends it sometimes divides into two smaller folds, which are lost on the sides of the foramen magnum.

The Arachnoid Membrane.

The arachnoid (*ἀράχνη εἶδος*, like a spider's web), so named from its extreme thinness, is a delicate membrane which envelops the brain, lying between the pia mater internally and the dura mater externally; from this latter membrane it is separated by a space, the *subdural space*.

It invests the brain loosely, being separated from direct contact with the cerebral substance by the pia mater, and a quantity of loose areolar tissue, the *subarachnoid space*. On the upper surface of the cerebrum the arachnoid is thin and transparent, and may be easily demonstrated by injecting a stream of air beneath it by means of a blowpipe; it passes over the convolutions without dipping down into the sulci between them. At the base of the brain the arachnoid is thicker, and slightly opaque toward the central part; it covers the anterior lobes, and extends across between the two temporo-sphenoidal lobes, so as to leave a considerable interval between it and the brain, the *anterior subarachnoid space*; it is in contact with the pons and under surface of the cerebellum, but between the hemispheres of the cerebellum and the medulla oblongata another considerable interval is left between it and the brain, called the *posterior subarachnoid space*. These two spaces communicate together across the crura cerebelli. The arachnoid membrane surrounds the nerves which arise from the brain, and encloses them in loose sheaths as far as their point of exit from the skull.

The *subarachnoid space* is the interval between the arachnoid and pia mater: this space is narrow on the surface of the hemispheres, but at the base of the brain a wide interval is left between the two temporo-sphenoidal lobes, and, behind, between the hemispheres of the cerebellum and the medulla oblongata. This space is the seat of an abundant serous secretion, the *cerebro-spinal fluid*, which fills up the interval between the arachnoid and pia mater. The subarachnoid space usually communicates with the general ventricular cavity of the brain by means of an opening in the inferior boundary of the fourth ventricle.

The subdural space also contains fluid; this is, however, small in quantity compared with the cerebro-spinal fluid.

Structure.—The arachnoid consists of bundles of white fibrous and elastic tissue intimately blended together. Its outer surface is covered with a layer of endothelium. From its inner surface are given off a number of bundles of fine connective tissue, which form a sponge-like trabecular network in the subarachnoid space, in the interstices of which the cerebro-spinal fluid is contained. Vessels of considerable size, but few in number, and, according to Boehdalek, a rich plexus of nerves derived from the motor division of the fifth, the facial, and the spinal accessory nerves, are found in the arachnoid.

The *cerebro-spinal fluid* fills up the subarachnoid space. It is a clear, limpid fluid, having a saltish taste and a slightly alkaline reaction. According to Lassaigne, it consists of 98.5 parts of water, the remaining 1.5 per cent. being solid matters, animal and saline. It varies in quantity, being most abundant in old persons, and is quickly reproduced. Its chief use is probably to afford mechanical protection to the nervous centres and to prevent the effects of concussions communicated from without.

The Pia Mater.

The pia mater is a vascular membrane, and derives its blood from the internal carotid and vertebral arteries. It consists of a minute plexus of blood-vessels, held together by an extremely fine areolar tissue. It invests the entire surface of the brain, dipping down between the convolutions and laminae, and is prolonged

into the interior, forming the velum interpositum and choroid plexuses of the fourth ventricle. Upon the surfaces of the hemispheres, where it covers the gray matter of the convolutions, it is very vascular, and gives off from its inner surface a multitude of minute vessels, which extend perpendicularly for some distance into the cerebral substance. At the base of the brain, in the situation of the anterior and posterior perforated spaces, a number of long straight vessels are given off, which pass through the white matter to reach the gray substance in the interior. On the cerebellum the membrane is more delicate, and the vessels from its inner surface are shorter. Upon the crura cerebri and pons Varolii its characters are altogether changed; it here presents a dense fibrous structure, marked only by slight traces of vascularity.

According to Fohmann and Arnold, this membrane contains numerous lymphatic vessels. Its nerves are derived from the sympathetic, and also from the third, fifth, sixth, facial, glosso-pharyngeal, pneumogastric, and spinal accessory. They accompany the branches of the arteries.

THE DIVISIONS OF THE BRAIN.

The brain (*encephalon*) is that portion of the cerebro-spinal axis which is contained in the cranial cavity. It is divided into four principal parts—viz. the cerebrum, the cerebellum, the pons Varolii, and the medulla oblongata.

The cerebrum forms the largest portion of the encephalon, and occupies a considerable part of the cavity of the cranium, resting in the anterior and middle fossæ of the base of the skull, and separated posteriorly from the cerebellum by the tentorium cerebelli. About the middle of its under surface is a narrow constricted portion, part of which, the *crura cerebri*, is continued onward into the pons Varolii below, and through it to the medulla oblongata and spinal cord; whilst another portion, the *crura cerebelli*, passes down into the cerebellum.

The cerebellum (*little-brain* or *after-brain*) is situated in the inferior occipital fossæ, being separated from the under surface of the occipital lobes of the cerebrum by the tentorium cerebelli. It is connected to the rest of the encephalon by means of connecting bands, called *crura*: of these, two ascend to the cerebrum, two descend to the medulla oblongata, and two blend together in front, forming the pons Varolii.

The pons Varolii is that portion of the encephalon which rests upon the upper part of the basilar process of the occipital bone and body of the sphenoid bone. It constitutes the bond of union of the various segments above named, receiving, above, the crura from the cerebrum; at the sides, the crura from the cerebellum; and below, the medulla oblongata.

The medulla oblongata extends from the lower border of the pons Varolii to the upper part of the spinal cord. It lies beneath the cerebellum, resting on the lower part of the basilar groove of the occipital bone.

Weight of the Encephalon.—The average weight of the brain in the adult male is 49½ oz., or a little more than 3 lbs. avoirdupois; that of the female 44 oz.; the average difference between the two being from 5 to 6 oz. The prevailing weight of the brain in the male ranges between 46 oz. and 53 oz., and in the female between 41 oz. and 47 oz. In the male the maximum weight out of 278 cases was 65 oz., and the minimum weight 34 oz. The maximum weight of the adult female brain, out of 191 cases, was 56 oz., and the minimum weight 31 oz. According to Luschka, the average weight of a man's brain is 1424 grammes (about 45 oz.), of a woman's 1272 grammes (about 41 oz.), and, according to Krause, 1570 grammes (about 48½ oz.) for the male, and 1350 (about 43 oz.) for the female. It appears that the weight of the brain increases rapidly up to the seventh year, more slowly to between sixteen and twenty, and still more slowly to between thirty and forty, when it reaches its maximum. Beyond this period, as age advances and the mental faculties decline, the brain diminishes slowly in weight, about an ounce for each subsequent decennial period. These results apply alike to both sexes.

The size of the brain was formerly said to bear a general relation to the intel-

lectual capacity of the individual. Cuvier's brain weighed rather more than 64 oz., that of the late Dr. Abercrombie 63 oz., and that of Dupuytren 62½ oz. On the other hand, the brain of an idiot seldom weighs more than 23 oz. But these facts are by no means conclusive, and it is well known that these weights have been equalled by the brains of persons who never displayed any remarkable intellect. Dr. Haldennan of Cincinnati has recorded the case of a mulatto, aged forty-five, whose brain weighed 68½ oz.; he had been a slave, and was never regarded as particularly intelligent; he was illiterate, but is said to have been reserved, meditative, and economical. Dr. Ensor, district medical officer at Port Elizabeth, reports that the brain of Carey, the Irish informer, weighed 61 oz. M. Nikiforoff has published an article on the subject of the weight of brains in the *Novosti*. According to him, the weight of the brain has no influence whatever on the mental faculties. It ought to be remembered that the significance of the weight of the brain should depend upon the proportion it bears to the dimensions of the whole body and to the age of the individual. It is equally important to know what was the cause of death, for long illness or old age exhausts the brain. To define the real degree of development of the brain it is therefore necessary to have a knowledge of the condition of the whole body, and, as this is usually lacking, the mere record of weight possesses little significance.

The human brain is heavier than that of all the lower animals, excepting the elephant and whale. The brain of the former weighs from eight to ten pounds; and that of a whale, in a specimen seventy-five feet long, weighed rather more than five pounds.

The Medulla Oblongata.

The **Medulla Oblongata**, or **bulb**, is the upper enlarged part of the spinal cord, and extends from the lower margin of the foramen magnum to the lower border of the pons Varolii. It is directed from above obliquely downward and backward; its anterior surface rests on the basilar groove of the occipital bone, its posterior surface is received into the fossa between the hemispheres of the cerebellum, forming the floor of the fourth ventricle. It is pyramidal in form, its broad extremity directed upward, its lower end being narrow at its point of connection with the cord. It measures an inch in length, three-quarters of an inch in breadth at its widest part, and half an inch in thickness. Its surface is marked, in the median line, in front and behind, by an *anterior* and *posterior median fissure*, which are continuous with those of the spinal cord. The anterior fissure contains a fold of pia mater, and terminates just below the pons in a *cul-de-sac*, the *foramen cecum*. It is interrupted at its lower part by some bundles of fibres, which cross obliquely from one side to the other, forming the decussation of the pyramids. The posterior is a deep but narrow fissure, continued upward to about the middle of the medulla, where it expands into the fourth ventricle. These two fissures divide the medulla into two symmetrical halves, each lateral half presenting elongated eminences which are continuous with the columns of the cord. By taking the lines along which some of the cranial nerves emerge from the medulla as landmarks, we may divide the surface of this portion of the nervous system into three columns, just in the same way as the spinal cord is divided into three columns by the lines corresponding to the points of exit of the anterior and posterior roots of the spinal nerves. The anterior column comprises that portion which is situated between the anterior median fissure and the fibres of origin of the hypoglossal nerve: this column is called the *pyramid*. The lateral column comprises that portion which is situated between the fibres of origin of the hypoglossal nerve and the fibres of origin of the glosso-pharyngeal, pneumogastric, and spinal accessory nerves. In the lower part of the medulla this column is single, and is called the lateral tract; but in the upper part an oval-shaped body comes forward between it and the pyramid, pushing aside the lateral tract. This is called the *olivary body*. The posterior column comprises that portion which is situated between the fibres of origin of the glosso-pharyngeal, pneumogastric, and spinal

accessory nerves, and the posterior median fissure. This column is marked by slight furrows marking off smaller columns, and these in the lower part of the medulla are named, from without inward, the *funiculus of Rolando*, the *funiculus cuneatus*, and the *funiculus gracilis*; in the upper part of the medulla the funiculus of Rolando and the funiculus cuneatus appear to become fused together, forming a single body called the *restiform body*.

The **Pyramids** are two pyramidal bundles of white matter, placed one on either side of the anterior median fissure, and separated from the olivary body, which is external to them, by a slight depression. At the lower border of the pons they are somewhat constricted; they then become enlarged, and taper as they descend, being continuous below, by their outer portion, with the anterior columns of the cord (*direct pyramidal tract*), and by their inner portion with the decussating fibres, seen in the anterior median fissure, which are derived from the lateral column of the cord (*crossed pyramidal tract*). For, on separating the pyramids below, it will be observed that their innermost fibres form from four to five bundles on each side, which decussate with one another across the anterior median fissure; this decussation, however, is not formed of fibres from the anterior column of the cord, but from the deep portion of the lateral columns which pass forward to the surface on the inner side of the anterior columns. The outermost fibres do not decussate; they are derived, as just stated, from the anterior column of the cord.

The **lateral column**, in the lower part of the medulla, is of the same width as the lateral column of the cord, and appears on the surface to be a direct continuation of it. In the upper part of the medulla the lateral tract, on account of the interpolation of the olivary body, is reduced to a narrow strip, lying between the olivary and restiform bodies.

The **olivary body** is a prominent oval mass, situated behind the pyramid, from which it is separated by a slight groove, along which the hypoglossal nerve arises. It is separated externally from the restiform body by a longitudinal narrow band of fibres, the continuation upward of the lateral tract, and by a groove from which the glosso-pharyngeal, pneumogastric, and spinal accessory nerves arise. It is equal in breadth to the pyramid; is a little broader above than below, and is about half an inch in length, being separated above from the pons Varolii by a slight depression, in which is sometimes to be seen a band of arched fibres. Numerous white fibres (*superficial arciform fibres*) are seen winding across the lower half of the pyramid and the olivary body to enter the restiform body.

The **funiculus of Rolando** is a longitudinal prominence, on the outer side of the lateral tract. It begins at the lower end of the medulla by a tapering extremity, and gradually enlarging as it ascends, forms at a level with the lower border of the olivary body a slight prominence, known as the *tubercle of Rolando*. About half an inch below the pons it appears to blend with the funiculus cuneatus. In front, it is separated from the lateral tract by a distinct groove, the continuation upward of the postero-lateral groove of the cord; behind, the separation from the funiculus cuneatus is much less distinct.

The **funiculus cuneatus** is the direct continuation upward of the posterior lateral column of the cord. It is situated between the funiculus of Rolando and the funiculus gracilis; it enlarges as it ascends, and forms, opposite the

FIG. 411.—Medulla oblongata and pons Varolii. Anterior surface.

lower extremity of the fourth ventricle, a slight eminence or enlargement, the *tuberculum cuneatum*, which is best marked in children. About half an inch below the pons it appears to blend with the funiculus of Rolando.

FIG. 412.—Posterior surface of the medulla oblongata.

median fissure. Opposite the apex of the fourth ventricle they form an enlargement (*clava*), and then diverging, form the lateral boundaries of the lower part of the fourth ventricle, and gradually tapering off they soon become no longer traceable.

The posterior surface of the medulla oblongata forms part of the floor of the fourth ventricle. This portion is of a triangular form, bounded on each side by the diverging funiculi graciles and restiform bodies, and is that part of the ventricle which, from its resemblance to the point of a pen, is called *calamus scriptorius*. The divergence of the funiculi graciles and restiform bodies opens to view the gray matter of the medulla, which is continuous below with the gray matter of the cord. In the middle line is seen a longitudinal furrow, which ends below, near the point of the calamus, in a somewhat cleft-like space, the *ventricle of Arantius*, which opens by a minute hole into the central canal of the cord.

The *arciform* or *arcuate fibres*, which have been mentioned as forming part of the restiform body, are found in the upper half of the medulla, both crossing its surface and traversing its substance. They are divided for the purpose of description into two sets—superficial and deep. The *superficial arciform fibres* have already been alluded to as crossing the pyramid and olivary body on each side. They emerge from the anterior median fissure, in which they can be traced to enter the raphe and cross it, after which they become no longer traceable. After emerging from the anterior median fissure they cross the pyramid and olivary body, and enter the restiform body. As they cross the olivary body they are reinforced

The *restiform bodies* appear on the surface to be the direct continuation upward of the funiculus of Rolando and the funiculus cuneatus. But they also receive the arched fibres (*arciform*), presently to be described, and fibres derived from the lateral column of the cord, or the *lateral cerebellar tract*. The restiform bodies are the largest prominences of the medulla, and are placed between the lateral tracts in front and the funiculus gracilis behind, from both of which they are separated by slight grooves. As they ascend they diverge from each other, assist in forming the lower part of the lateral boundaries of the fourth ventricle, and then enter the corresponding hemisphere of the cerebellum, forming its inferior peduncles.

The *funiculus gracilis* is the direct continuation upward of the posterior median column of the cord. It is a narrow white cord, placed parallel to and along the side of the posterior median fissure. It is separated from the funiculus cuneatus below and the restiform body above by a slight groove, which is continuous with the groove on the surface of the cord, which marks off the posterior median column. It consists entirely of white fibres, and is the direct continuation of the posterior median column of the cord. At first the funiculi of the two sides lie in close contact on either side of the posterior

by some of the deep arciform fibres which come to the surface on the inner side of, or through, this structure. The *deep arciform fibres* are described with the Microscopic Anatomy of the Medulla.

Structure.—The medulla oblongata, like the spinal cord, consists of both gray and white matter, and exhibits in sections both these structures arranged in certain definite masses. The fibres of the several columns of the cord enter the medulla, and in it undergo a rearrangement, some of them passing through it to the pons Varolii, the cerebrum, and the cerebellum, while others end in its gray substance. Some fibres take origin in the medulla, and are continued onward to the cerebrum and cerebellum. The structure of the medulla will be best understood by tracing its several parts upward from the spinal cord.

The **pyramid** is composed of fibres derived from the direct pyramidal tract of the anterior column of the cord of its own side, and from the crossed pyramidal tract of the lateral column of the opposite half of the cord. Those fibres which are derived from the direct pyramidal tract, and which in the cord lie close to the median fissure, are in the medulla placed to the outer side of the pyramid, being pushed aside, as it were, by the interpolation of the fibres derived from the crossed pyramidal tract, which are much more numerous. The crossed pyramidal fibres ascend from the lateral column of the spinal cord, and, passing through the anterior gray cornua and across the median fissure, form the inner part of the pyramid. The fibres of the pyramid may be traced upward through the pons to the *crus cerebri* of its own side. All the fibres of the anterior column of the cord are not continued into the pyramid of the medulla; some of them pass backward, and enter the *formatio reticularis*, which is described with the Microscopic Anatomy of the Medulla.

The **olivary body** when cut across obliquely is seen to be composed, externally of white fibres, internally of a gray layer, the *corpus dentatum*, which is arranged in the form of a hollow capsule, open at its upper and inner part and presenting a zigzag or dentated outline. White fibres enter the interior of this capsule by the aperture at its upper and inner part, constituting the *olivary peduncle*.

The **lateral tract of the medulla** is the continuation upward of the lateral column of the cord. The fibres from it divide into three sets: one set, the most numerous, pass deeply behind the olivary body, and ascend through the *formatio reticularis* to the pons; a second set pass across the anterior median fissure to join the pyramid, forming the *crossed pyramidal set*; the third set, few in number, form a small band, which passes backward to the restiform body to enter the cerebellum, forming the *lateral cerebellar tract*.

The **funiculus of Rolando**, which is a longitudinal prominence on the outer side of the lateral tract, is now seen to be the enlarged head of the posterior cornu of the gray matter, which is displaced laterally in consequence of the increase in size of the posterior columns of the medulla, so that it lies almost at right angles to the posterior median fissure, and approaching the surface forms a prominence which is covered over by a very thin layer of white matter derived from the funiculus cuneatus. Its most prominent part on the surface is called the *tubercle of Rolando*.

The **funiculus cuneatus** is the direct continuation upward of the posterolateral column of the cord. Its white fibres are derived from this region of the cord. The fibres appear to end in the gray matter which forms the so-called nucleus of this column; this nucleus, at first narrow, gradually enlarges, and produces, externally, the eminence mentioned above as the *tuberculum cuneatum*.

The **funiculus gracilis** is the direct continuation upward of the posterior median column of the cord. It consists entirely of white fibres, which are continuous with those of this region of the cord. Like the funiculus cuneatus, its fibres appear to end in its so-called nucleus, which produces externally the prominence mentioned above as the *clava*.

The **restiform body** is mainly constituted by the fusing together of the funiculus

of Rolando and the funiculus cuneatus, to which are added the arciform fibres of the medulla and the lateral cerebellar tract from the lateral tract of the medulla. In addition to these, a bundle of fibres has been described by Solly as passing from the anterior column of the cord obliquely upward below the olivary body to the restiform body. The white fibres of the restiform body are continued upward to the cerebellum, forming its inferior peduncle.

Microscopic Anatomy of the Medulla.—If the cranial nerves emerging from the medulla are traced into its substance, it will be seen that they divide each hemisphere of the medulla into three wedge-shaped areas, which have been named the anterior, lateral, and posterior areas of the medulla.

The *anterior area* comprises that portion which is situated between the anterior median fissure and the fibres of origin of the hypoglossal nerve. On the surface of the medulla this area corresponds to the pyramid.

The *lateral area* comprises that portion which is situated between the fibres of origin of the hypoglossal nerve and the fibres of origin of the glosso-pharyngeal, pneumogastric, and spinal accessory nerves. On the surface of the medulla, in its lower part, this area is single, and is called the lateral tract; but in the upper part an oval-shaped body comes forward between it and the pyramid, pushing aside the lateral tract. This oval-shaped body is the olivary body.

The *posterior area* comprises that portion which is situated between the fibres of origin of the glosso-pharyngeal, pneumogastric, and spinal accessory nerves and the posterior median fissure. On the surface of the medulla, this area is marked by slight furrows marking off smaller columns; these, in the lower part of the medulla, are named, from without inward, the funiculus of Rolando, the funiculus cuneatus, and the funiculus gracilis; in the upper part of the medulla the funiculus of Rolando and the funiculus cuneatus appear to become fused together, forming a single body, called the restiform body.

The Arciform Fibres.—*Deep Set.*—The deep arciform fibres are more numerous than the superficial set; they traverse the whole area of the upper half of the medulla, except the pyramid. They pass from the raphe: some become superficial and join the superficial arciform fibres; while others remain deep and pass to the restiform body and to the nuclei of the funiculus cuneatus and funiculus gracilis.

The Raphe.—The raphe is situated in the middle line of the medulla, above the decussation of the pyramids. It consists of nerve-fibres intermingled with nerve-cells. The fibres have different directions which can only be seen in suitable microscopic sections; thus:

1. Some are antero-posterior; these are continuous in front with the superficial arciform fibres.
2. Some are longitudinal; these are derived from the arciform fibres, which on entering the raphe change their direction and become longitudinal.
3. Some are oblique; these are continuous with the deep arciform fibres which pass from the raphe.

Some of the fibres of the raphe arise from the nuclei on the floor of the fourth ventricle.

The Formatio Reticularis.—In the substance of the medulla behind the pyramid and olivary body is a peculiar reticulated structure, which has received the name of *formatio reticularis*; the appearance it presents in sections of the medulla is due to its being composed of bundles of fibres running at right angles to each other, some being longitudinal, others transverse.

The longitudinal fibres are derived—

1. From the anterior column of the cord after the direct pyramidal tract has passed into the pyramid.
2. From the olivary body.
3. From the lateral column of the cord after the crossed pyramidal tract has passed into the pyramid.
4. From the funiculus cuneatus and funiculus gracilis.

The transverse fibres are the deep arciform fibres.

In the lateral part of this reticular structure gray matter containing large nerve-cells is found.

The Gray Matter of the Medulla Oblongata.—The gray matter of the medulla oblongata is partly continuous with the gray matter of the cord, and partly arranged in independent masses. It contains many multipolar ganglion-cells. In the lower part of the medulla the gray matter, which is continuous with that of the cord, is arranged in the shape of two crescentic horns, with their convexities toward each other, and connected by a central commissure; but in the upper part it loses its crescentic arrangement, becomes more abundant, and is disposed with less regularity.

The caput of the posterior horns becomes enlarged, and gradually shifted

FIG. 413.—Section of the medulla oblongata at about the middle of the olivary body. (Schwalbe.)

outward, so that they form rounded masses, close under the lateral tract, and produce the prominence on the surface called the funiculus of Rolando. The neck of the cornu diminishes in size, and is broken up into a reticular formation by the passage of longitudinal and transverse fibres through it, so that the caput is separated from the rest of the gray matter.

As the central canal expands into the fourth ventricle, the rest of the posterior horn of gray matter is pushed outward into the funiculus cuneatus and funiculus gracilis; in each of these funiculi it forms a distinct accumulation of gray matter, constituting the nucleus cuneatus and the nucleus gracilis.

The anterior horn of gray matter is broken up by the passage through it of the crossed pyramidal tract from the lateral column of the cord. By this means the anterior portion of the horn is completely isolated from the remainder, and constitutes the lateral nucleus of gray matter which is situated near the surface of the lateral tract.

The greater part of the rest of the anterior horn, being permeated by the decussating fibres, presents a reticular formation. A small part of the base of the anterior cornu comes to the surface of the floor of the fourth ventricle, and is

exposed to view by the divergence of the funiculus cuneatus and funiculus gracilis. It forms a continuous mass, which gradually increases in size and forms the eminence of the fasciculus teres.

In it is a group of nerve-cells, which form the nucleus from which the roots of the hypoglossal nerve arise.

At the base of the posterior cornu, in the lower part of the medulla, is a group of cells, which, if traced upward, are found to be pushed on one side: so that in the floor of the fourth ventricle they are outside the hypoglossal nucleus and form a second eminence, the *ala cinerea*: from it arise the roots of the accessory portion of the spinal accessory, pneumogastric, and glosso-pharyngeal nerves. Outside this, again, and toward the upper part of the medulla, is another group of cells, from which most of the fibres of the auditory nerve take origin.

Another independent mass of gray matter is found in the olivary body, forming the corpus dentatum. It consists of a gray layer arranged in the form of a hollow capsule, open at its upper and inner part, and presenting a zigzag or dentated outline. White fibres enter the interior of this capsule by the aperture at its upper and inner part, constituting the olivary peduncles. Some of these fibres terminate in the cells of the corpus dentatum, while others are continued through the gray layer to join the arciform fibres. Furthermore, two small isolated bands of gray matter are seen, one on the dorsal and the other on the mesial aspect of the corpus dentatum: these are known as *accessory olivary nuclei*.

The Pons Varolii.

The **pons Varolii** (*tuber annulare*) is the bond of union of the various segments of the encephalon, connecting the cerebrum above, the medulla oblongata below, and the cerebellum behind. It is situated above the medulla oblongata, below the crura cerebri, and between the hemispheres of the cerebellum.

Its *anterior surface* presents a broad transverse band of white fibres, which arches like a bridge across the upper part of the medulla, extending between the two hemispheres of the cerebellum. This surface projects considerably beyond the level of these parts, is of quadrangular form, rests upon the clivus of the sphenoid bone, and is limited before and behind by very prominent margins. It presents along the middle line a longitudinal groove, wider in front than behind, which lodges the basilar artery: numerous transverse striæ are also observed on each side, which indicate the course of its superficial fibres.

Its *posterior surface* forms part of the floor of the fourth ventricle.

At each side its fibres become contracted into a thick rounded cord, the *crus cerebelli*, which enters the substance of the cerebellum, constituting its middle peduncle.

Structure.—The pons Varolii consists of two parts, which differ in appearance and structure from each other: the anterior or ventral half consists for the most part of fibres arranged in transverse and longitudinal bundles with a small amount of gray matter: the posterior or dorsal half is a continuation of the reticular formation of the medulla with the gray matter of the floor of the fourth ventricle. The anterior or ventral half consists of three layers of fibres: (1) superficial transverse fibres; (2) superficial longitudinal fibres; (3) deep transverse fibres. These three layers are not, however, completely differentiated from each other, for some transverse fibres may be seen between the bundles of the longitudinal fibres. The superficial transverse fibres (Fig. 414) pass from the crus or middle peduncle of the cerebellum to the median raphe of the pons, where they meet and interlace with those coming from the opposite side. They then dip deeply into the substance of the pons and pass to the crus cerebri of the opposite side. The superficial longitudinal fibres enter the pons below as a single mass, being the continuation upward of the fibres of the pyramids of the medulla; as they ascend they become broken up into bundles by some of the transverse fibres passing through them, and are continued into the superficial portion of the crus cerebri, much increased in

number from being reinforced by the fibres derived from the nerve-cells in the deep transverse strata.

The deep transverse fibres form a much thicker layer than the superficial set, and contain much gray matter between them. The fibres pass from the crus or middle peduncle of the cerebellum to the median raphe of the pons, where they meet and interlace with those coming from the opposite side.

The posterior or dorsal portion of the pons is chiefly constituted by a continuation upward of the reticular formation of the medulla and by the gray matter of the floor of the fourth ventricle.

Microscopic Anatomy of the Pons.—This presents the same reticular structure as in the medulla, consisting of longitudinal fibres continued upward from the medulla, with interlacing transverse fibres, between which is interspersed gray

FIG. 414.—Superficial dissection of the medulla oblongata and pons. (Ellis.)

matter with nerve-cells, especially in the deeper layers. Many of the deep transverse fibres join the nerve-cells, which are situated in the gray matter (*nuclei pontis*) of this layer. From these cells other fibres are given off which ascend through the pons to the crus cerebri.

In the lower part of this portion of the pons is a small isolated collection of gray matter, the *superior olivary nucleus*, enclosed by some of the deep transverse fibres, called the *trapezium*. It is situated close to the medulla, behind the superficial longitudinal fibres from the pyramid and immediately above the olivary body. The fibres of the trapezium, which are probably connected with the cells of the nucleus, pass to the middle peduncle of the cerebellum. Near the floor of the fourth ventricle important collections of nerve-cells are found, from which some of the cranial nerves arise. One of these forms the nucleus of the sensory root of the fifth nerve; a second, the nucleus of the motor part of the same nerve; a third, the nucleus of the sixth nerve; and a fourth, the nucleus of the facial nerve. The nucleus of the auditory nerve, situated just at the junction of the pons and medulla, is prolonged upward into the pons.

Septum.—The posterior part of the pons is subdivided into lateral halves by a medium septum, but this does not extend into the anterior half, being here obliterated by the transverse fibres. It is formed mainly by the decussation and change in the direction of fibres as they cross the middle line.

The Cerebrum (Fig. 415).

The **cerebrum** constitutes the largest portion of the encephalon. Its under surface or base is of an irregular form, resting in front on the anterior and middle fossæ of the skull, behind upon the tentorium cerebelli. Its upper surface is of an ovoid form, broader behind than in front, convex in its general outline, and

FIG. 415.—Upper surface of the brain, the arachnoid having been removed.

divided into lateral halves or hemispheres, right and left, by the *great longitudinal fissure*, which extends throughout the entire length of the cerebrum in the middle line, reaching down to the base of the brain in front and behind, but interrupted in the middle by a broad transverse commissure of white matter, the *corpus callosum*, which connects the two hemispheres together. This fissure lodges the *falx cerebri*, and indicates the original development of the brain by two lateral halves.

Each hemisphere presents an outer surface, which is convex to correspond with the vault of the cranium; an inner surface, which is flattened, and in contact with the opposite hemisphere (the two inner surfaces forming the sides of the longitudinal fissure); and an under surface or base, of an irregular form, which rests in front on the anterior and middle fossæ of the base of the skull, and behind upon the tentorium cerebelli.

Upper Surface of the Cerebrum.

If the arachnoid and pia mater are removed, the entire surface of each hemisphere will be seen to present a number of depressions (*fissures* and *sulci*) separating a number of convoluted eminences (the *convolutions* or *gyri*).

The depressions are of two kinds, *fissures* and *sulci*. The *fissures* are few in number; they are constant in their arrangement, and are produced by the foldings of the cerebrum during the process of development. They involve both gray and white matter. The *sulci* are more numerous; they are superficial depressions of the gray matter, which is folded inward and only indents the central white substance; they vary in different brains and in different parts of the same brain.

The Convolutions.—There is no accurate resemblance between the convolutions in different brains, nor are they exactly symmetrical on the two sides of the same brain, but their general arrangement or plan is fairly constant. Certain infoldings of the cerebrum take place at an early period of development and form important landmarks, which are constant and can without difficulty be recognized, but the secondary depressions and convolutions vary considerably.

The number and extent of the convolutions, as well as their depth, appear to bear a close relation to the intellectual power of the individual, as is shown in their increasing complexity of arrangement as we ascend from the lowest mammalia up to man. Thus they are absent in some of the lower orders of mammalia, and they increase in number and extent through the higher orders. In man they present the most complex arrangement. Again, in the child at birth before the intellectual faculties are exercised the convolutions have a very simple arrangement, presenting few undulations, and the sulci between them are less deep than in the adult. In old age, when the mental faculties have diminished in activity, the convolutions become much less prominently marked.

The convolutions on the outer convex surface of the hemisphere are the largest and most complicated convolutions of the brain; their general direction is more or less oblique; they frequently branch like the letter Y in their course upward and backward toward the longitudinal fissure; these convolutions attain their greatest development in man, and are especially characteristic of the human brain.

Structure of the Convolutions.—The outer surface of each convolution, as well as the sides and bottom of the sulci between them, are composed of gray matter, which is here called the *cortical substance*. The interior of each convolution is composed of white matter, and white fibres also blend with the gray matter at the sides and bottom of the sulci. By this arrangement the convolutions are adapted to increase the amount of gray matter without occupying much additional space, while they also afford a greater extent of surface for the termination of the white fibres in gray matter.

The Lobes and Fissures of the Brain.—Each hemisphere of the brain on its external surface is divided into five lobes, the division being made by the main fissures and by imaginary lines drawn to connect them (Fig. 416).

The fissures dividing the five lobes on the external surface of the hemispheres are three in number, and are named *fissure of Sylvius*, *fissure of Rolando*, and *parieto-occipital fissure*.

The *fissure of Sylvius* begins at the base of the brain at the anterior perforated space, and passes outward to the external surface of the hemisphere. It gives off a short *anterior limb*, which passes forward, and another, *ascending limb*, which passes upward into the inferior frontal convolution. It is then continued backward as the *horizontal limb*, and terminates in the parietal lobe after curving upward for a short distance. It separates the frontal and parietal lobes from the temporo-sphenoidal, and occupies the middle third of the lateral surface of the hemisphere.

The *fissure of Rolando* is situated about the middle of the outer surface of the hemisphere. It commences at or near the longitudinal fissure, and runs downward and forward to terminate a little above the horizontal limb of the fissure of Sylvius,

and about half an inch behind the ascending limb of the same fissure. It separates the frontal from the parietal lobe.

The **parieto-occipital fissure** is only seen to a slight extent on the outer surface of the hemisphere, and is not so distinctly marked as the others. The portion on the outer surface of the hemisphere is sometimes called the *external parieto-occipital fissure*, to distinguish it from the continuation of the sulcus on the internal surface of the hemisphere, which would then be termed the *internal parieto-occipital fissure*. It commences about midway between the posterior extremity of the brain and the fissure of Rolando, and runs downward and forward for about an inch. It divides the parietal and occipital lobes.

These three fissures divide the external surface of the hemisphere into five lobes—the *frontal*, the *parietal*, the *occipital*, the *temporo-sphenoidal*, and the *central* or *island of Reil*.

The **frontal lobe** is that portion of the brain which is situated in front of the

FIG. 416.—Convulsions and fissures of the outer surface of the cerebral hemisphere.

fissure of Rolando and above the horizontal limb of the fissure of Sylvius. Its under surface rests on the orbital plate of the frontal bone, and is termed the *orbital lobe*.

The outer surface of the frontal lobe presents three sulci, which divide it into four primary convolutions: 1. The *precentral sulcus* runs upward through this lobe, parallel to the lower half of the fissure of Rolando. It divides off a convolution which lies between it and the fissure of Rolando, and which is called the *ascending frontal convolution*. 2 and 3. From it two sulci, the *superior* and *inferior frontal sulci*, run forward and downward, and divide the remainder of the outer surface of the lobe—namely, that part in front of the precentral sulcus—into three principal convolutions, named respectively the *superior*, *middle*, and *inferior frontal convolutions*.

The under surface of the frontal lobe, which rests on the orbital plate of the

frontal bone, is named the *orbital lobe* (Fig. 417). It presents a well-marked groove or sulcus for the olfactory tract. The convolution internal to this sulcus forms part of the marginal gyrus, hereafter to be described. External to the sulcus this surface of the frontal lobe is divided into three convolutions by a well-marked sulcus, the *orbital sulcus*. These are named, from their positions, the *internal*, *anterior*, and *posterior orbital convolutions*, and are the continuation respectively of the superior, middle, and inferior frontal convolutions.

The *ascending frontal convolution* is a simple convolution, bounded in front by the precentral sulcus, behind by the fissure of Rolando, and extending from the

FIG. 417.—Convolution and fissures of the under surface of the anterior lobe.

upper margin of the hemisphere above to a little behind the bifurcation of the fissure of Sylvius below.

The *superior frontal convolution* is situated between the margin of the longitudinal fissure and the superior frontal sulcus. It extends above on to the inner aspect of the hemisphere, forming the marginal convolution, and in front on to the orbital surface, forming the internal orbital convolution. It is much divided by secondary sulci.

The *middle frontal convolution* is situated between the superior and inferior frontal sulci, and extends from the precentral sulcus to the lower margin of the lobe, where it forms the anterior orbital convolution.

The *inferior frontal convolution* is situated below the inferior frontal sulcus, and extends from the lower part of the precentral sulcus, circling round the ascending and anterior limbs of the fissure of Sylvius, to the under surface of the lobe, where it forms the posterior orbital convolution.

The *parietal lobe* is situated between the frontal and occipital lobes, and is not

much more than half the size of the former. It is bounded in front by the fissure of Rolando; behind, by the external parieto-occipital fissure and a line drawn in continuation of that sulcus over the hemisphere; and below, by the horizontal limb of the fissure of Sylvius and a line connecting this with the lower end of the superior occipital sulcus. Above, it extends to the longitudinal fissure. It presents for examination two sulci and three convolutions.

The *intraparietal sulcus* commences close to the horizontal limb of the fissure of Sylvius, about midway between the fissure of Rolando and the upturned extremity of the fissure of Sylvius. It first runs upward parallel to and behind the lower half of the fissure of Rolando, and then turns backward, extending nearly to the termination of the external parieto-occipital fissure, where it sometimes becomes continuous with the superior occipital sulcus. The ascending portion of this sulcus separates off a convolution, the *ascending parietal*, which lies between it and the fissure of Rolando, whilst the horizontal portion divides the remainder of the parietal lobe into two other convolutions, the *superior* and *inferior parietal*.

The *post-central sulcus* is a slightly marked groove, which is sometimes a branch of the intraparietal sulcus, being given off where the ascending portion of this sulcus turns backward. It lies parallel to and behind the upper part of the fissure of Rolando, and separates the ascending from the superior parietal convolution.¹

The *ascending parietal convolution* is bounded in front by the fissure of Rolando, behind by the ascending portion of the intraparietal and the post-central sulci. It extends from the great longitudinal fissure above to the horizontal limb of the fissure of Sylvius below. It lies parallel with the ascending frontal convolution, with which it is connected below, and also generally above, the termination of the fissure of Rolando.

The *superior parietal convolution* is bounded in front by the post-central sulcus, which separates it from the previous convolution, but with which it is usually connected above the upper extremity of the sulcus; behind, it is bounded by the external parieto-occipital fissure, below the termination of which it is connected with the occipital lobe by a narrow convolution, the *first annectant gyrus*. Below, it is separated from the inferior parietal convolution by the horizontal portion of the intraparietal sulcus; and above it is continuous on the inner surface of the hemisphere with the quadrate lobe.

The *inferior parietal convolution* is that portion of the parietal lobe which is situated between the ascending portion of the intraparietal sulcus in front, the horizontal portion of the same sulcus above, the horizontal limb of the fissure of Sylvius below, and the posterior boundary of the parietal lobe behind. It is subdivided into two convolutions by an indistinct groove. One, the *supramarginal*, lies behind the lower end of the intraparietal sulcus and above the horizontal limb of the fissure of Sylvius. It is connected, in front, with the ascending parietal convolution beneath the intraparietal sulcus, and with the superior temporo-sphenoidal convolution behind, round the posterior extremity of the fissure of Sylvius. The other, the *angular*, is connected in front with the foregoing, and with the middle temporo-sphenoidal convolution by a process which curves round the supe-

¹ Professor Cunningham describes these two sulci, intraparietal and post-central, somewhat differently. He regards them as both belonging to the intraparietal sulcus, which he divides into three parts: the ascending portion of the intraparietal, as described above, he terms the *ramus verticalis inferior*; the horizontal portion as the *ramus horizontalis*; while the post-central sulcus he denominates the *ramus verticalis superior*. He states that considerable variability is exhibited in the relation to each other of these different parts of the intraparietal sulcus, but that the one in which the three parts of the sulcus are confluent is by far the most constant condition. Sometimes, however, the three parts of the sulcus may be all separate, or the *ramus horizontalis* confluent with the *ramus verticalis inferior*, the *ramus verticalis superior* remaining separate; or, again, the vertical limbs may be confluent and the horizontal limb separate; or, finally, the *ramus horizontalis* may be joined to the lower end of the *ramus verticalis superior*, while the lower vertical limb is separate. The connection which sometimes exists between the intraparietal sulcus and the occipital lobe he calls the *ramus occipitalis*. In the majority of cases, however, the occipital ramus is separated from the main portion of the intraparietal sulcus by a superficial or deep bridging convolution (*Journal of Anatomy and Physiology*, vol. xxiv. part ii. p. 135).

rior temporo-sphenoidal or parallel sulcus. It is connected with the occipital lobe by the *second annectant gyrus*.

The **occipital lobe** is triangular in shape and forms the posterior extremity of the hemisphere. It is bounded in front by the external parieto-occipital fissure and a line drawn from the extremity of this in the direction of the fissure across the outer surface of the hemisphere. It is continuous below and in front with the temporo-sphenoidal lobe, and above with the parietal. It is divided on the outer surface of the hemisphere into three convolutions by two indistinct sulci—the *superior* and *middle occipital sulci*. They are directed backward across the lobe, being frequently small and ill-marked; the superior is sometimes continuous with the horizontal portion of the intraparietal sulcus.

The *superior occipital convolution* is situated above the superior sulcus, and is connected to the superior parietal convolution by the *first annectant gyrus*.

The *middle occipital convolution* is situated between the superior and middle occipital sulci, and is connected to the angular convolution by the *second annectant gyrus*, and to the middle temporo-sphenoidal by the *third annectant gyrus*.

The *inferior occipital convolution* is situated below the middle occipital sulcus, and is sometimes separated from the external occipito-temporal convolution on the under surface of the hemisphere by an inconstant sulcus, the *inferior occipital sulcus*. It is connected to the inferior temporo-sphenoidal convolution by the *fourth annectant gyrus*.

The **temporo-sphenoidal lobe** is that portion of the hemisphere which is lodged in the middle fossa of the base of the skull. In front and above it is limited by the fissure of Sylvius; behind, it is connected with the parietal and occipital lobes, and is limited artificially by a line continuing the direction of the external parieto-occipital fissure across the outer surface of the hemisphere. It is divided into three convolutions by two sulci. The superior of these runs parallel to the horizontal limb of the fissure of Sylvius. It is named the *superior temporo-sphenoidal* or *parallel sulcus*, and it is well marked and constant. The second, the *middle temporo-sphenoidal*, is not so well marked or constant; it takes the same course at a lower level.

The *superior temporo-sphenoidal convolution* is situated between the horizontal limb of the fissure of Sylvius and the superior temporo-sphenoidal sulcus. It is continuous behind with the supramarginal convolution.

The *middle temporo-sphenoidal convolution* is situated between the superior and middle sulci of the same name, and is continuous behind with the angular and middle occipital convolutions.

The *inferior temporo-sphenoidal convolution* is situated below the middle temporo-sphenoidal sulcus, and is separated from the external occipito-temporal convolution, on the under surface of the hemisphere, by a sulcus which is called the inferior temporo-sphenoidal sulcus. It is connected with the inferior occipital convolution.

The **central lobe**, or **island of Reil** (Fig. 417), is situated in the fissure of Sylvius, at the base of the brain; it is separated, in front, from the posterior orbital convolution by a nearly transverse sulcus, the *anterior sulcus of Reil*; externally, from the inferior frontal convolution and the lower ends of the ascending frontal and parietal convolutions by another deep sulcus, the *external sulcus of Reil*; and posteriorly, from the temporo-sphenoidal lobe, by a third sulcus, the *posterior sulcus of Reil*. It is a triangular-shaped prominent cluster of about six convolutions, the *gyri operi*, so called from being covered in by the fissure. By the removal of these convolutions the extraventricular part of the corpus striatum would be reached.

On the *inner* or *median surface of the hemispheres* the arrangement of the convolutions is less complex; they are generally well defined, and some of them being of great length, there is not the same subdivision into smaller lobes as on the external surface (Fig. 418). The fissures in the internal surface are five in

number, and are named the *calloso-marginal*, the *parieto-occipital*, the *calcarine*, the *collateral*, and the *dentate*.

The **calloso-marginal fissure** is seen in front, commencing below the anterior extremity of the corpus callosum; it at first runs forward and upward, parallel with the rostrum of the corpus callosum, and, winding round the genu of that body, it continues from before backward, between the upper margin of the hemisphere and the convolution of the corpus callosum, to about midway between the anterior and posterior extremities of the brain, where it turns upward to reach the upper margin of the inner surface of the hemisphere a short distance behind the superior extremity of the furrow of Rolando. It separates the marginal convolution from the gyrus fornicatus or convolution of the corpus callosum.

The **parieto-occipital fissure** (*internal parieto-occipital*) is the continuation of the fissure of the same name seen on the outer surface of the hemisphere. It

FIG. 418.—Convolutions and fissures of the inner surface of the cerebral hemisphere.

extends in an oblique direction downward and forward to join the calcarine fissure on a level with the hinder end of the corpus callosum. It separates the quadrate from the cuneate lobe.

The **calcarine fissure** commences, usually by two branches, at the back of the hemisphere, runs nearly horizontally forward, and is joined by the parieto-occipital fissure, and continues nearly as far as the posterior extremity of the corpus callosum, to terminate a little below the level of this commissure. It separates the cuneate lobe from the uncinat gyrus, and causes the prominence known as the hippocampus minor or calcar avis, whence its name.

The **collateral fissure** is situated below the preceding, being separated from it by the uncinat gyrus. It runs forward, from the posterior extremity of the brain, nearly as far as the commencement of the fissure of Sylvius. It runs between the internal and external occipito-temporal convolutions. It lies below the posterior and middle horn of the lateral ventricle, and causes the prominence known as the eminentia collateralis.

The **dentate** or **hippocampal fissure** commences immediately below the posterior extremity of the corpus callosum, and runs forward to terminate at the recurved part of the uncinat gyrus. It corresponds with the prominence of the hippocampus major in the descending horn of the lateral ventricle.

The lobes or convolutions seen on the internal surface of the hemisphere are

six in number, and are named *gyrus fornicatus*, *marginal*, *quadrate*, *cuneate*, *uncinate*, or *internal occipito-temporal*, and the *external occipito-temporal*.

The **gyrus fornicatus**, or convolution of the corpus callosum, is a well-marked lobe which begins just in front of the anterior perforated space at the base of the brain; it ascends in front of the genu of the corpus callosum, and runs backward along the upper surface of this body to its posterior extremity, where it joins the uncinate convolution. It is bounded above in the greater part of its extent by the calloso-marginal fissure, which separates it from the marginal convolution; behind the spot where this fissure turns upward it is continuous with the quadrate lobe.

The **marginal convolution** is situated above the preceding, and has received its

name from its position along the border of the hemisphere. It commences in front of the anterior perforated space, runs along the margin of the longitudinal fissure on the under surface of the orbital lobe, being bounded externally by the sulcus for the olfactory tract; it then turns upward to the upper surface of the hemisphere and runs backward, forming the marginal convolution, on the inner surface, to the point where the calloso-marginal fissure turns upward to reach the superior border of the hemisphere.

The **quadrate lobe** (*precuneus*) is the marginal convolution of the longitudinal fissure behind the calloso-marginal sulcus, lying between this fissure in front and the internal parieto-occipital behind. It joins the gyrus fornicatus below, and is continuous above with the superior parietal convolution.

The **cuneate** or **occipital lobule** is triangular in shape, being situated between the internal parieto-occipital and calcarine fissures, which, as above mentioned, meet behind the posterior extremity of the gyrus fornicatus.

The **uncinate** or **internal occipito-temporal convolution** extends from the posterior extremity of the hemisphere to the fissure of Sylvius, being bounded

above by the calcarine and dentate fissure, and separated below from the external occipito-temporal convolution by the collateral fissure. From the anterior extremity a narrow portion is recurved or bent backward in the form of a hook, which is sometimes called the *crochet* or *uncus*. The back part of this convolution—that is, the part below the calcarine fissure—is sometimes known as the *lingual lobule* or *gyrus*.

The **external occipito-temporal convolution** is of considerable length, and lies between the collateral fissure and the inferior temporo-sphenoidal sulcus, which

FIG. 420.—Top view of the brain of man, showing the localization of various functions. (After Ferrier.) References the same as in the preceding figure.

latter separates it from the inferior temporo-sphenoidal convolution on the outer surface of the hemisphere.

Besides the great primary convolutions above named and described, and which can be recognized in almost any well-developed brain, there are a great number of secondary convolutions which pass from one primary convolution to another, and often render the arrangement of the latter somewhat obscure; of these, the connections of the occipital lobe, above mentioned, and which are named *annectant convolutions*, may be taken as examples.

Cerebral Localization and Topography.—Within the last few years physiological and pathological research have gone far to prove that the surface of the brain may be mapped out into series of definite areas, each one of which is intimately connected with some well-defined function. And this is especially true with regard to the convolutions on either side of the fissure of Rolando, which are believed by most physiologists of the present day to be concerned in motion, those grouped around the fissure being associated with movements of the extremities of the opposite side of the body, and those around the lower end of the fissure being related to movements of the mouth and tongue.

This is not the place, nor can space be given, to describe these localities. But the two accompanying woodcuts from Ferrier (Figs. 419, 420) have been introduced, and will serve to indicate the position of these areas as far as they have been at present ascertained.

The relation of the principal fissures and convolutions of the cerebrum to the outer surface

of the scalp has been the subject of much recent investigation, and many systems have been devised by which one may localize these parts from an examination of the external surface of the head.

These plans can only be regarded as approximately correct for several reasons: in the first place, because the relations of the convolutions and sulci to the surface are found to be very variable in different individuals; secondly, because the surface area of the scalp is greater than the surface area of the brain, so that lines drawn on the one cannot correspond exactly to sulci or convolutions on the other; and thirdly, because the sulci and convolutions in two individuals are never precisely alike. Nevertheless, the principal fissures and convolutions can be mapped out with sufficient accuracy for all practical purposes, so that any particular convolution can be generally exposed by removing with the trephine a certain portion of the skull's area.

The various landmarks on the outside of the skull, which can be easily felt, and which serve

FIG. 421.—Drawing to illustrate cranio-cerebral topography. (Macalister.) Taken from a cast prepared by Professor Cunningham.

as indications of the position of the parts beneath, have been already referred to (see page 224), and the relation of the fissures and convolutions to these landmarks is as follows:

Longitudinal Fissure.—This corresponds to a line drawn from the glabella at the root of the nose to the external occipital protuberance.

The Fissure of Sylvius.—The position of the fissure of Sylvius and its horizontal limb is marked by a line starting from a point one inch and a quarter horizontally behind the external angular process of the frontal bone to a point three-quarters of an inch below the most prominent point of the parietal eminence. The first three-quarters of an inch will represent the main fissure, the remainder the horizontal limb. The bifurcation of the fissure is, therefore, two inches behind and about a quarter of an inch above the level of the external angular process. The ascending limb of the fissure passes upward from this point parallel to, and immediately behind, the coronal suture.

Fissure of Rolando.—To find the upper end of the fissure of Rolando, a measurement should be taken from the glabella to the external occipital protuberance. The position of the top of the sulcus will be, measuring from in front, 55.6 per cent. of the whole distance from the glabella to the external occipital protuberance. Professor Thane adopts a somewhat simpler method. He divides the distance from the glabella to the external occipital protuberance over the top of the head into two equal parts, and, having thus defined the middle point of the ver-

The *inferior frontal fissure* follows the course of the superior temporal ridge on the frontal bone.

The *intraparietal fissure* begins on a level with the junction of the middle and lower third of the fissure of Rolando, on a line carried across the head from the back of the root of one auricle to that of the other. After passing upward it curves backward, lying parallel to the longitudinal fissure, midway between it and the parietal eminence; it then curves downward to end midway between the posterior fontanelle and the parietal eminence.

Under Surface or Base of the Cerebrum (Fig. 423).

The under surface of each hemisphere presents a subdivision into three lobes, named, from their position, *anterior*, *middle*, and *posterior*.

The *anterior* or *frontal lobe*, of a triangular form, with its apex backward, is

FIG. 423.—Base of the brain.

somewhat concave, and rests upon the convex surface of the roof of the orbit, being separated from the middle lobe by the fissure of Sylvius. The *middle lobe*, which is more prominent, is received into the middle fossa of the base of the skull, and comprises the under part of the temporo-sphenoidal lobe. The *posterior* or *occipital lobe* rests upon the tentorium, its extent forward being limited by the anterior margin of the cerebellum.

The various objects exposed to view on the under surface of the cerebrum, in and near the middle line, are here arranged in the order in which they are met with from before backward:

Longitudinal fissure.	Optic commissure.
Corpus callosum and its peduncles.	Tuber cinereum.
Lamina cinerea.	Infundibulum.
Olfactory tract.	Pituitary body.
Fissure of Sylvius.	Corpora albicantia.
Anterior perforated space.	Posterior perforated space.

Crura cerebri.

The **longitudinal fissure** partially separates the two hemispheres from each other: it divides the two frontal lobes in front, and on raising the cerebellum and pons it will be seen completely separating the two occipital lobes. Of these two portions of the longitudinal fissure, that which separates the occipital lobes is the longer. The intermediate portion of the fissure is filled up by the great transverse band of white matter, the *corpus callosum*. In the fissure between the two frontal lobes the anterior cerebral arteries ascend on the corpus callosum.

The **corpus callosum** terminates at the base of the brain by a concave margin which is connected with the tuber cinereum through the intervention of a thin layer of gray substance, the *lamina cinerea*. This may be exposed by gently raising and drawing back the optic commissure. A white band may be observed on each side, passing from the under surface of the corpus callosum, backward and outward to the commencement of the fissure of Sylvius: these bands are called the *peduncles of the corpus callosum*. They may be traced upward around the genu to become continuous with the *striae longitudinales*, or *nerves of Lancisi*, on the upper surface of the corpus callosum (page 732). Laterally, this portion of the corpus callosum extends into the frontal lobe.

The **lamina cinerea** is a thin layer of gray substance, extending backward above the optic commissure from the termination of the corpus callosum to the tuber cinereum; it is continuous on each side with the gray matter of the anterior perforated space, and forms the anterior part of the inferior boundary of the third ventricle.

The **olfactory tract**, with its bulb, is seen on each side of the longitudinal fissure upon the under surface of each frontal lobe.

The **fissure of Sylvius** separates the frontal from the temporo-sphenoidal lobe, and lodges the middle cerebral artery. It begins at the outer side of a depression, at the bottom of which is the anterior perforated space. This depression is called the *vallecula Sylvii*. At its commencement is seen a point of medullary substance, corresponding to a subjacent band of white fibres, connecting the frontal and temporo-sphenoidal lobes, and called the *fasciculus unciformis*. On following this fissure outward, it divides into two branches, enclosing portions of the frontal and parietal lobes, which overhang and cover the upper part of a prominent cluster of isolated convolutions called the *island of Reil* or *central lobe*. The overhanging portion of the frontal and parietal lobe is called the *operculum of the insula*.

The **anterior perforated space** is situated at the inner side of the fissure of Sylvius. It is of a triangular shape, bounded in front, by the orbital convolutions of the frontal lobe and the roots of the olfactory tract; behind, by the optic tract; externally, by the temporo-sphenoidal lobe and commencement of the fissure of Sylvius; internally, it is continuous with the lamina cinerea and crossed by the peduncle of the corpus callosum. It is of a grayish color, and corresponds to the under surface of the corpus striatum, a large mass of gray matter situated in the interior of the brain; it has received its name from being perforated by numerous minute apertures for the transmission of small straight vessels into the substance of the corpus striatum, constituting the antero-median and antero-lateral ganglionic branches of the anterior and middle cerebral arteries.

The **optic commissure** is situated in the middle line, immediately in front of the tuber cinereum and below the lamina cinerea.¹ It is the point of junction between the two optic nerves.

¹ That is to say, the commissure is superficial to the lamina in the order of dissection when the base is uppermost.

Immediately behind the diverging optic tracts, and between them and the peduncles of the cerebrum (*crura cerebri*), is a lozenge-shaped interval, the *interpeduncular space*, in which are found the following parts: the tuber cinereum, infundibulum, pituitary body, corpora albicantia, and the posterior perforated space.

The **tuber cinereum** is an eminence of gray matter situated between the optic tracts and the corpora albicantia; it is connected with the surrounding parts of the cerebrum, forms part of the floor of the third ventricle, and is continuous with the gray substance in that cavity. From the middle of its under surface a conical tubular process of gray matter, about two lines in length, is continued downward and forward, to be attached to the posterior lobe of the pituitary body: this is the *infundibulum*. Its canal, which is funnel-shaped, communicates with the third ventricle.

The **pituitary body** (*hypophysis cerebri*) is a small reddish-gray vascular mass weighing from five to ten grains, and of an oval form, situated in the sella Turcica, in connection with which it is retained by a process of dura mater derived from the inner wall of the cavernous sinus. This process covers in the pituitary fossa, enclosing the pituitary body, and having a small hole in its centre through which the infundibulum passes.

Structure.—The pituitary body is very vascular, and consists of two lobes, separated from one another by a fibrous lamina. Of these, the anterior is the larger, of an oblong form and somewhat concave behind, where it receives the posterior lobe, which is round. The two lobes differ both in development and structure. The *anterior lobe*, of a dark, yellowish-gray color, is developed from the ectoderm of the buccal cavity, and resembles to a considerable extent, in microscopic structure, the thyroid body. It consists of a number of isolated vesicles and slightly convoluted alveoli lined by epithelium and united together by connective tissue. The epithelium is columnar, and occasionally ciliated. The alveoli sometimes contain a colloid material, similar to that found in the thyroid body, and their walls are surrounded by a close network of lymphatics and capillary blood-vessels. The *posterior lobe* is developed by an outgrowth from the embryonic brain, and during foetal life contains a cavity which communicates through the infundibulum with the cavity of the third ventricle. In the adult it becomes firmer and more solid, and consists of a sponge-like connective tissue arranged in the form of reticulating bundles, between which are branched cells, some of them containing pigment. In the lower animals the two lobes are quite distinct, and it is only in the mammalia that they become connected together.

The **corpora albicantia**, or **mammillaria**, are two small, round, white masses, each about the size of a pea, placed side by side immediately behind the tuber cinereum. They are formed by the anterior crura of the fornix, hence called the *bulbs of the fornix*, which, after descending to the base of the brain, are folded upon themselves before passing upward to the thalami optici. They are composed externally of white substance and internally of gray matter, the gray matter of the two being connected by a transverse commissure of the same material. At an early period of foetal life they are blended together into one large mass, but become separated about the seventh month.

The **posterior perforated space** (*pons Varini*) corresponds to a whitish-gray substance placed between the corpora albicantia in front, the pons Varolii behind, and the crura cerebri on each side. It forms the back part of the floor of the third ventricle. It is perforated by numerous small orifices for the passage of the postero-median ganglionic branches of the posterior cerebral and posterior communicating arteries.

The **crura cerebri** (*peduncles of the cerebrum*) are two thick cylindrical bundles of white matter which emerge from the anterior border of the pons and diverge as they pass forward and outward to enter the under part of either hemisphere. Each crus is about three-quarters of an inch in length, and somewhat broader in front than behind. They are marked upon their surface with longitudinal striæ,

and each is crossed, just before entering the hemisphere, by a flattened white band, the *optic tract*, which is adherent by its upper border to the peduncle. The third nerve may be seen emerging from a groove on the inner side of each crus, and the fourth nerve winding round its outer side from above.

Structure of the Crura.—Each crus consists of a superficial layer of longitudinal white fibres, the *crusta*, continued upward from the pons; of a deeper layer, a prolongation of the reticular formation, termed the *tegmentum*; and of an intermediate stratum of gray matter, the *locus niger*.

The *crusta*, or the superficial layer of longitudinal fibres, consists of coarse bundles of nerve-fibres which are collected on the under or free surface of the crus. It is formed almost entirely of longitudinal fibres continuous with the pyramidal fibres of the medulla and pons, those derived from the medulla occupying the central portion of the crusta, those added in the pons being placed laterally. The fibres pass to the cerebral hemispheres, entering the internal capsule.

The *tegmentum* forms the deeper part of the crus cerebri, and is united below with its fellow of the opposite side by a prolongation of the septum of the pons, but separated above by the posterior perforated space. It consists of longitudinal bundles of white fibres interlaced by transverse fibres, together with a quantity of gray matter with scattered nerve-cells. It forms a well-marked *formatio reticularis* similar to that found in the pons and medulla, with which it is continuous, receiving, however, a bundle of fibres (*superior peduncle*) from the cerebellum. Above, the fibres enter the optic thalamus.

The *locus niger* is a mass of gray matter situated between the crusta and tegmentum, and projecting here and there between the bundles of the former. It is thicker at the inner than at the outer side, and is traversed in its mesial part by the fibres of origin of the third nerve. It contains irregular nerve-cells, in which are lodged numerous dark pigment-granules.

The posterior lobes of the cerebrum are concealed from view by the upper surface of the cerebellum and pons Varolii. When these parts are raised, the two hemispheres are seen to be separated by the great longitudinal fissure, this fissure being interrupted by the posterior rounded border of the corpus callosum.

General Arrangement of the Parts composing the Cerebrum.

As the peduncles or crura of the cerebrum enter the hemispheres they diverge from one another, so as to leave an interval between them, the *interpeduncular space*. As they ascend the component fibres of each pass through two large masses of gray matter, the ganglia of the brain, called the *thalamus opticus* and *corpus striatum*, which project as rounded eminences from the upper and inner side of each peduncle. The hemispheres are connected together, above these masses, by the great transverse commissure, the *corpus callosum*; the interval left between its under surface, the upper surface of the ganglia, and the parts closing the interpeduncular space forms the general ventricular cavity. The upper part of this cavity is subdivided into two by a vertical septum, the *septum lucidum*; and thus the two lateral ventricles are formed. The lower part of the cavity forms the third ventricle, which communicates with the lateral ventricles above and with the fourth ventricle behind. The fifth ventricle is the interval left between the two layers composing the septum lucidum.

The Interior of the Cerebrum.

If the upper part of either hemisphere is removed with a scalpel about half an inch above the level of the corpus callosum, its internal white matter will be exposed. It is an oval-shaped centre, of white substance, surrounded on all sides by a narrow convoluted margin of gray matter, which presents an equal thickness in nearly every part. This white central mass has been called the *centrum ovale minus*. Its surface is studded with numerous minute red dots (*puncta vasculosa*), produced by the escape of blood from divided blood-vessels. In inflammation or

great congestion of the brain these are very numerous and of a dark color. If the remaining portion of one hemisphere is slightly separated from the other, a broad band of white substance will be observed connecting them at the bottom of the longitudinal fissure; this is the *corpus callosum*. The margins of the hemispheres which overlap this portion of the brain are called the *labia cerebri*. Each labium is part of the convolution of the corpus callosum (*gyrus fornicatus*), already described, and the space between it and the upper surface of the corpus callosum has been termed the *ventricle of the corpus callosum* (Fig. 427).

The hemispheres should now be sliced off to a level with the corpus callosum, when the white substance of that structure will be seen connecting the two hemispheres. The large expanse of medullary matter now exposed, surrounded by the convoluted margin of gray substance, is called the *centrum ovale majus* of Vieussens.

The *corpus callosum* is a thick stratum of transverse fibres exposed at the bottom of the longitudinal fissure. It connects the two hemispheres of the brain,

FIG. 424.—Section of the brain. Made on a level with the corpus callosum.

forming their great transverse commissure, and forms the roof of a space in the interior of each hemisphere, the *lateral ventricle*. It is about four inches in length, extending to within an inch and a half of the anterior, and to within two inches and a half of the posterior, part of the brain. It is somewhat broader behind than in front, and is thicker at either end than in its central part, being thickest behind. It presents a somewhat arched form (Fig. 431, 5) from before backward, terminating anteriorly in a rounded border, which curves, downward and backward, between the frontal lobes to the base of the brain. In its course it forms a distinct bend, named the *genu*, and is then continued downward and

backward to the base of the brain, where it is connected, through the lamina cinerea, with the tuber cinereum. The reflected portion of the corpus callosum is called the *beak* or *rostrum*: it becomes gradually narrower as it descends, and is attached by its lateral margins to the frontal lobes. At its termination the corpus callosum gives off two bundles of white substance, which, diverging from one another, pass backward, across the anterior perforated space, to the entrance of the fissure of Sylvius. They are called the *peduncles of the corpus callosum*. Posteriorly, the corpus callosum forms a thick rounded fold, called the *splenium* or *pad*, which is free for a little distance as it curves forward, and is then continuous with the fornix. On its upper surface the structure of the corpus callosum is very apparent, being collected into coarse transverse bundles. Along the middle line is a linear depression, the *raphe*, bounded laterally by two or more slightly elevated longitudinal bands, called the *striae longitudinales* or *nerves of Lancisi*; and, still more externally, other longitudinal striae are seen beneath the convolutions which rest on the corpus callosum. These are the *striae longitudinales laterales* or *tæniæ tectæ*. The under surface of the corpus callosum is continuous behind with the fornix, being separated from it in front by the septum lucidum, which forms a vertical partition between the two ventricles. On each side the fibres of the corpus callosum extend into the substance of the hemispheres, connecting them together. The greater thickness of the two extremities of this commissure is explained by the fact that the fibres from the anterior and posterior parts of each hemisphere cannot pass directly across, but have to take a curved direction.

An incision should now be made through the corpus callosum on either side of the raphe, when two large irregular-shaped cavities will be exposed, which extend through a great part of the length of each hemisphere. These are the lateral ventricles.

The **lateral ventricles** are serous cavities, formed by the upper part of the general ventricular space in the interior of the brain. They are lined by a thin diaphanous lining membrane (the *ependyma*), covered by nucleated epithelium, with cilia scattered here and there in patches. It is moistened by a serous fluid, which is sometimes, even in health, secreted in considerable quantity. These cavities are two in number, one in each hemisphere, and they are separated from each other by a vertical septum, the *septum lucidum*.

Each lateral ventricle consists of a central cavity, or *body*, and three smaller cavities or *cornua*, which extend from it in different directions. The anterior cornu curves forward and outward into the substance of the frontal lobe. The posterior cornu, called the *digital cavity*, curves backward into the occipital lobe. The middle cornu descends into the temporo-sphenoidal lobe.

The *central cavity*, or body of the lateral ventricle, is triangular in form. It is bounded, above, by the under surface of the corpus callosum, which forms the roof of the cavity. Internally is a vertical partition, the *septum lucidum*, which separates it from the opposite ventricle, and connects the under surface of the corpus callosum with the fornix. Its floor is formed by the following parts, enumerated in their order of position from before backward: the *corpus striatum*, *tænia semicircularis*, *optic thalamus*, *choroid plexus*, *fornix*, and commencement of its *corpus fimbriatum*.

The *anterior cornu* is triangular in form, passing outward into the frontal lobe and curving round the anterior extremity of the corpus striatum. It is bounded, above, by the corpus callosum; below and externally, by the corpus striatum; and in front, by the reflected portion of the corpus callosum.

The *posterior cornu*, or *digital cavity*, curves backward into the substance of the occipital lobe, its direction being backward and outward, and then inward. On its inner wall is seen a longitudinal eminence, which is produced by the extension inward of the calcarine sulcus; this is called the *hippocampus minor*, or *calcar avis*. Between the middle and posterior horns a smooth eminence is observed which varies considerably in size in different subjects. It is called the *eminentia collateralis*.

The *middle* or *descending cornu*, the largest of the three, traverses the middle lobe of the brain, forming in its course a remarkable curve round the back of the optic thalamus. It passes, at first, backward, outward, and downward, and then curves round the *crus cerebri*, forward and inward, nearly to the point of the middle lobe, close to the fissure of Sylvius. Its upper boundary, or roof, is formed by the fibres of the corpus callosum, passing downward and outward into the temporo-sphenoidal lobe, with which are incorporated the posterior fibres of the nucleus caudatus and *tænia semicircularis*, which are prolonged into it. Its lower boundary, or floor, presents for examination the following parts: the *hippocampus major*, *pes hippocampi*, *eminentia collateralis* or *pes accessorius*, *corpus fimbriatum* of the *fornix*, *choroid plexus*, *fascia dentata*, *transverse fissure*.

The *corpus striatum* has received its name from the striped appearance which

FIG. 425.—The lateral ventricles of the brain.

its section presents, in consequence of diverging white fibres being mixed with the gray matter which forms the greater part of its substance. The greater portion of this body is imbedded in the white substance of the hemisphere, and is therefore external to the ventricle. It is termed the *extraventricular portion*, or the *nucleus lenticularis*; a part, however, is visible in the ventricle and its anterior cornu; this is the *intraventricular portion*, or the *nucleus caudatus*. The intraventricular portion is a pear-shaped mass of gray matter: its broad extremity is directed forward into the fore part of the body and anterior cornu of the lateral ventricle; its narrow end is directed outward and backward, and lies on the outer side of the optic thalamus, and is continued into the roof of the descending cornu; it is covered by the serous lining of the cavity and crossed by some veins of considerable size. It is separated from the extraventricular portion by a lamina of

white matter, which is called the *internal capsule*, in contradistinction to a lamina of white matter which covers the outer surface of the extraventricular portion of the corpus striatum, and which is called the *external capsule*. The internal capsule is formed by fibres of the crista of the crus cerebri, supplemented by fibres derived from the nuclei on each side. In horizontal section it is seen to be somewhat abruptly curved, with its convexity inward; the prominence of the curve is called the *genu*, and projects between the intraventricular portion of the corpus striatum and the optic thalamus (Fig. 426). The extraventricular portion of the corpus striatum, or nucleus lenticularis, is oval in form. It does not extend as far forward or backward as the nucleus caudatus. It is bounded externally by a lamina of white matter called the *external capsule*, which is covered on its outer surface

FIG. 426.—Middle part of a horizontal section through the cerebrum at the level of the dotted line in the small figure of one hemisphere. (From Ellis, after Dalton.)

by a thin layer of gray matter termed the *claustrum*. The claustrum presents ridges and furrows on its outer surface, corresponding to the convolutions and sulci of the island of Reil, with the white matter of which it is in immediate relation.

The *tænia semicircularis* is a narrow, whitish, semi-transparent band of medullary substance situated in the depression between the nucleus caudatus and optic thalamus. Anteriorly, it descends, in connection with the anterior pillar of the fornix, to below the level of the foramen of Monro, where it enters a mass of gray matter, the *nucleus amygdalæ*. Behind, it is continued into the roof of the middle or descending horn of the lateral ventricle, and is lost near the bottom of the cornua. Beneath it is a large vein (*vena corporis striati*), which receives numerous small veins from the surface of the corpus striatum and optic thalamus, and joins the *venæ Galeni*.

The **choroid plexus** is a highly vascular, fringe-like membrane, occupying the margin of the fold of pia mater (*velum interpositum*) in the interior of the brain. It extends, in a curved direction, across the floor of the lateral ventricle. In front, where it is small and tapering, it communicates with the choroid plexus of the opposite side through an oval aperture, the *foramen of Monro*. Posteriorly, it descends into the middle horn of the lateral ventricle, where it joins with the pia mater through the transverse fissure. In structure it consists of minute and highly vascular villous processes, composed of large round corpuscles, containing, besides a central nucleus, several yellowish granules and fat-molecules, and covered by a single layer of flattened epithelium. The arteries of the choroid plexus enter

FIG. 427.—Transverse vertical section of the brain, through the fore part of the foramen magnum, looked at from the front. (After Hirschfeld and Leveillé.)

the ventricle at the descending cornu, and, after ramifying through its substance, send branches into the substance of the brain. The veins of the choroid plexus terminate in the *venæ Galeni*.

The **corpus fimbriatum** (*tenia hippocampi*) is a narrow, white, tape-like band situated immediately behind the choroid plexus. It is the thin lateral edge of the posterior pillar of the fornix, and is attached along the inner border of the hippocampus major as it descends into the middle horn of the lateral ventricle. It may be traced as far as the *crochet* or hook of the uncinæ convolution.

The *optic thalamus* and *fornix* will be described on a subsequent page.

The middle cornu should now be exposed throughout its entire extent, by introducing the little finger gently into it, and cutting outward along the finger through the substance of the hemisphere, which should be removed to an extent sufficient to expose the entire cavity.

The **hippocampus major**, or **cornu Ammonis** (Fig. 428), so called from its resemblance to a ram's horn, is a white eminence, of a curved elongated form, extending throughout the entire length of the floor of the middle horn of the lateral ventricle. At its lower extremity it becomes enlarged, and presents a number of rounded elevations with intervening depressions, which, from presenting some resemblance to the paw of an animal, is called the *pes hippocampi*. If a transverse section is made through the hippocampus major (Fig. 427), it will be seen that this

eminence is produced by the extension inward of the dentate (hippocampal) sulcus on the exterior of the brain. This sulcus is filled with gray substance, which projects along the free margin of the hippocampus major, forming a notched ridge, the *fascia dentata*. The hippocampus is covered on its ventricular surface by a thin lamina of gray matter, which is continuous with the corpus fimbriatum of the fornix.

The *eminentia collateralis*, or *pes accessorius*, has already been mentioned as a white eminence, varying in size, placed between the hippocampus major and hippocampus minor, at the junction of the posterior with the descending cornu. It is formed by the protrusion inward of the collateral fissure.

Fascia Dentata.—On separating the inner border of the corpus fimbriatum from the choroid plexus, and raising the edge of the former, a serrated band of gray substance, the edge of the gray substance in the dentate fissure, will be seen beneath it: this is the *fascia dentata*. Correctly speaking, it is placed external to the cavity of the descending cornu.

The **transverse fissure** is of a horseshoe shape, extending from the end of the descending cornu on one side to the same point on the opposite side. Its

FIG. 428.—Transverse section of the middle horn of the lateral ventricle. (From a drawing by Mr. F. A. Barton.)

horizontal portion (which extends from the commencement of the descending cornu on one side to the same point on the opposite side) is bounded, above, by the splenium, or rounded posterior extremity of the corpus callosum and the fornix; below, by the corpora quadrigemina, pineal gland, and the posterior extremity of the optic thalamus. Its lateral portions curve downward, forward, and inward, and are bounded above by the crura cerebri and optic thalamus, below by the hippocampus major and the corpus fimbriatum of the fornix. Through this fissure the pia mater passes from the exterior of the brain into the ventricles, to form the velum interpositum and the choroid plexuses. Where the pia mater projects into the lateral ventricle, beneath the edge of the fornix, it is connected with the lining membrane of these cavities, so as to exclude all communication with the exterior of the brain.

The **septum lucidum** (Fig. 431, 6) forms the internal boundary of the lateral ventricles. It is a thin, semitransparent septum, attached, above, to the under surface of the corpus callosum; below, to the anterior part of the fornix; and, in front of this, to the reflected portion of the corpus callosum. It is triangular in form, broad in front, and narrow behind, its surfaces looking toward the cavities of the ventricles. The septum consists of two laminæ, separated by a narrow interval, the *fifth ventricle*.

Fifth Ventricle.—The fifth ventricle was originally a part of the great longitudinal fissure, which has become shut off by the union of the hemispheres in the formation of the corpus callosum above and the fornix below. Its walls are therefore formed by the median wall of the hemispheres, and consist of an internal layer of gray matter, derived from the gray matter of the cortex and an external layer of white substance continuous with the white matter of the cerebral hemispheres. This is lined on its external surface by the ependyma of the lateral ventricles. The fifth ventricle is not lined by epithelium. In the fœtus and in some animals this space communicates, below, with the third ventricle, but in the adult it forms a separate cavity. In cases of serous effusion into the ventricles the septum is often found softened and partially broken down.

The fifth ventricle may be exposed by cutting through the septum and attached portion of the corpus callosum with scissors: after its examination the corpus callosum should be cut across, toward its anterior part, and the two portions carefully dissected, the one forward, the other backward, when the fornix will be exposed.

The **fornix** (Figs. 425, 431) is a longitudinal lamella of white fibrous matter situated beneath the corpus callosum, with which it is continuous behind, but separated in front by the septum lucidum. It may be described as consisting of two symmetrical halves, one for either hemisphere. These two portions are joined together in the middle line, where they form the *body*, but are separated from one another in front and behind, forming the *anterior* and *posterior crura*.

The *body of the fornix* is triangular; narrow in front, broad behind. Its upper surface is connected, in the median line, to the septum lucidum in front and the corpus callosum behind, while laterally this surface forms part of the floor of each lateral ventricle. Its under surface rests upon the velum interpositum, which separates it from the third ventricle, and the inner portion of the optic thalami. Its outer edge, on each side, is in contact with the choroid plexuses.

The *anterior crura* arch downward toward the base of the brain, separated from each other by a narrow interval. They are composed of white fibres, which descend through a quantity of gray matter in the lateral walls of the third ventricle, and are placed immediately behind the anterior commissure. At the base of the brain the white fibres of each crus form a sudden curve upon themselves, and spread out and form the outer part of the corresponding *corpus albicans*, from which point they may be traced upward into the substance of the corresponding optic thalamus (Fig. 431). The anterior crura of the fornix are connected in their course with the peduncle of the pineal gland and the superficial fibres of the *tænia semicircularis*, and receive fibres from the septum lucidum.

Between the anterior crura or pillars of the fornix and the anterior extremities of the optic thalami an oval aperture is seen on each side: this is the *foramen of Monro* (Fig. 430). The two openings descend toward the middle line and lead into the upper part of the third ventricle. Through these openings the lateral ventricles on each side communicate with the third ventricle, and consequently with each other.

The *posterior crura*, at their commencement, are intimately connected by their upper surfaces with the corpus callosum; diverging from one another, they pass downward into the descending horn of the lateral ventricle, being continuous with the concave border of the hippocampus major. The lateral thin edges of the posterior crura have received the name of *corpus fimbriatum*. Upon examining the under surface of the fornix, between its diverging posterior crura, a triangular portion of the under surface of the corpus callosum may be seen. On it are a number of lines, some transverse, others longitudinal or oblique. This portion has been termed the *lyra*, from the fancied resemblance it bears to the strings of a harp.

Divide the fornix across anteriorly, and reflect the two portions, the one forward, the other backward, when the velum interpositum will be exposed.

The **velum interpositum** (Fig. 429) is a vascular membrane, a prolongation from

the pia mater into the interior of the brain through the transverse fissure, passing beneath the posterior rounded border of the corpus callosum and fornix, and above the corpora quadrigemina, pineal gland, and optic thalami. It is of a triangular form, and separates the under surface of the body of the fornix from the cavity of the third ventricle. Its posterior border forms an almost complete investment for the pineal gland. Its anterior extremity, or apex, is bifid: each bifurcation has attached to it the anterior extremity of the choroid plexus of the lateral ventricle through the foramen of Monro. On its under surface are the *choroid plexuses of the third ventricle*. To its lateral margins are connected the choroid plexuses of the lateral ventricles. Of the arteries of the velum interpositum some branches

FIG. 429.—The fornix, velum interpositum, and middle or descending cornu of the lateral ventricle.

from the superior cerebellar and posterior cerebral enter from behind beneath the corpus callosum; another constant branch, the anterior choroid, enters the velum interpositum at the extremity of the middle horn of the lateral ventricle, and supplies this structure and the choroid plexus. The veins of the velum interpositum, the *venæ Galeni*, two in number, run between its layers; they are formed by the *venæ corporis striati* and the veins of the choroid plexuses; the *venæ Galeni* unite posteriorly into a single trunk, which terminates in the straight sinus (Fig. 383).

The velum interpositum should now be removed. This must be effected carefully, especially at its posterior part, where it invests the pineal gland: the optic thalami will then be exposed, with the cavity of the third ventricle between them (Fig. 430).

The **optic thalami** are two large oblong masses, placed between the diverging portions of the corpora striata; they are of a white color superficially; internally

they are composed chiefly of gray matter. Each thalamus rests upon its corresponding crus cerebri, which it embraces. *Externally*, it is separated from the corpus striatum by the tænia semicircularis. *Internally*, it forms the lateral boundary of the third ventricle, and running along its upper and inner border is seen the peduncle of the pineal gland. Its *upper surface* is free, being partly seen in the lateral ventricle; it is partially covered by the velum interpositum and fornix, and marked in front by an eminence, the *anterior tubercle*. Its *under surface* is united with the tegmentum of the crus cerebri. Its *posterior extremity* projects above the level of the corpora quadrigemina and crus cerebri, and internally forms a well-marked prominence, the *posterior tubercle* or *pulvinar*, and below and outside this it presents two small rounded eminences, the *internal* and *external geniculate bodies*. Its *anterior extremity*, which is narrow, forms the posterior boundary of the foramen of Monro.

FIG. 430.—The third and fourth ventricles. An arrow has been placed in the position of the foramen of Monro.

The **Third Ventricle** is the narrow oblong fissure placed between the optic thalami and extending to the base of the brain. It is bounded, above, by the under surface of the velum interpositum, from which are suspended the choroid plexuses of the third ventricle. Its floor, somewhat oblique in its direction, is formed, from before backward, by the parts which are contained in the interpeduncular space—viz. the lamina cinerea, the tuber cinereum and infundibulum, the corpora albicantia and the locus perforatus posticus—and behind these by the tegmenta of the crura cerebri; its sides are formed by the optic thalami, along the upper and inner border of which are two white tracts, one on each side, the *peduncles of the pineal gland*. It is bounded, in front, by the anterior crura of the

fornix and part of the anterior commissure; behind, by the posterior commissure and the *iter a tertio ad quartum ventriculum*.

The cavity of the third ventricle is crossed by three commissures, named, from their position, *anterior*, *middle*, and *posterior*.

The *anterior commissure* is a round bundle of white fibres, placed in front of the anterior crura of the fornix, and appears to connect together the corpora striati. It passes outward through the corpus striatum on each side, and then curves backward into the substance of the temporo-sphenoidal lobe.

The *middle or soft commissure* consists almost entirely of gray matter. It connects together the optic thalami, and is continuous with the gray matter lining the anterior part of the third ventricle. It is frequently broken in examining the brain, and might then be supposed to be wanting.

The *posterior commissure*, smaller than the anterior, is a flattened white band of fibres, and appears to connect together the optic thalami posteriorly. It consists of decussating fibres which come from the tegmentum of the crus cerebri on one side, and pass through the optic thalami, across the back part of the third ventricle, to the white substance of the temporo-sphenoidal lobe of the other side. Some of the fibres may also serve as commissural fibres between the optic thalami. It bounds the third ventricle posteriorly, above the opening of the Sylvian aqueduct. The pineal gland is placed above it and connected to its upper surface.

The third ventricle has four openings connected with it. In front are the two oval apertures of the foramina of Monro, one on each side, through which the third communicates with the lateral ventricles. Behind is a third opening, leading into the fourth ventricle by a canal, the *aqueduct of Sylvius*, or *iter a tertio ad quartum ventriculum*. The fourth, situated in the anterior part of the floor of the ventricle, is a deep pit, which leads downward to the funnel-shaped cavity of the infundibulum (*iter ad infundibulum*). A fifth opening existed in the fœtus, which communicated behind with a cavity in the pineal gland. A sixth opening also existed in the fœtus, which communicated in front with the fifth ventricle.

The lining membrane of the lateral ventricles is continued through the foramen of Monro into the third ventricle, and extends along the *iter a tertio* into the fourth ventricle; at the bottom of the *iter ad infundibulum* it ends in a *cul-de-sac*.

The **foramen of Monro** is a foramen by which each lateral ventricle communicates with the third ventricle. It is formed by the anterior extremity of the body of the fornix, which, dividing into its two crura, arches downward in front of the anterior extremity of the optic thalami; the crus is not, however, in contact with the thalamus, but an interval is left between the two, which is the foramen of Monro. Its boundaries are, therefore, in front, the anterior pillars of the fornix; behind, the anterior extremity of the optic thalamus; above, the body of the fornix; and below, the groove between the anterior pillars of the fornix and the optic thalamus.

Behind the third ventricle, and in front of the cerebellum, are the corpora quadrigemina, and, resting upon these, the pineal gland.

The **pineal gland** (*epiphysis cerebri*), so named from its peculiar shape (*pinus*, a fir-cone), is a small reddish-gray body, conical in form (hence its synonym, *conarium*), placed immediately behind the posterior commissure and between the nates, upon which it rests. It is retained in its position by a duplicature of pia mater, derived from the under surface of the velum interpositum, which almost completely invests it. The pineal gland is about four lines in length and from two to three in width at its base, and is said to be larger in the child than in the adult, and in the female than in the male. Its base is connected to the cerebrum by two peduncles (the *peduncles of the pineal gland*), which pass forward upon the upper and inner margin of the optic thalami to the anterior crura of the fornix, with which they become blended; these two peduncles join together at their posterior extremity, in front of the pineal gland, forming a sort of festoon, and

the base of the gland is connected to their posterior margin at the point of junction. In front the band of union is joined to the posterior commissure.

Structure.—The pineal gland consists of a number of follicles lined by epithelium and connected together by ingrowths of connective tissue. The follicles contain a transparent viscid fluid, and a quantity of sabulous matter, named *acervulus cerebri*, composed of phosphate and carbonate of lime, phosphate of magnesia and ammonia, with a little animal matter. These concretions are almost constant in their existence, and are found at all periods of life. When

this body is solid the sabulous matter is found upon its surface, and occasionally upon its peduncles.

On the removal of the pineal gland and adjacent portion of the pia mater the corpora quadrigemina are exposed.

The **corpora** or **tubercula quadrigemina** (*optic lobes*) are four rounded eminences placed in pairs, two in front and two behind, and separated from one another by a crucial depression. They are situated immediately behind the third ventricle and posterior commissure, and beneath the posterior border of the corpus callosum. Below, they are separated in the middle line from the crura cerebri by the aqueduct of Sylvius, but on each side are continuous with the tegmentum of the crura. The anterior or upper pair, the *nates*, are the larger, oblong from before backward, and of a gray color. The posterior or lower pair, the *testes*, are

hemispherical in form, and lighter in color than the preceding. From the outer side of each of these eminences a prominent white band, termed *brachium*, is continued forward and outward. Those from the nates (*brachia anteriora*) are the larger, and pass obliquely outward, between the inner and outer geniculate bodies, into the optic tract. Those from the testes (*brachia posteriora*) pass beneath an oval prominence, the internal geniculate body, and are no longer traceable. Both pairs, in the adult, are quite solid, being composed of white matter externally and gray matter within. These bodies are larger in the lower animals than in man. In fishes, reptiles, and birds they are only two in number, are called the *optic lobes*, from their connection with the optic nerves, and are hollow in their interior; but in mammalia they are four in number, as in man, and quite solid. In the human foetus they are developed at a very early period, and form a large proportion of the cerebral mass; at first they are only two in number, as in the lower vertebrata, and hollow in their interior.

These bodies are connected with the cerebellum by means of a large white cord on each side, the *processus ad testes*, or superior peduncles of the cerebellum, which is continued onward to the optic thalami through the tegmentum of the crus cerebri. Beneath the corpora quadrigemina some fibres from it decussate with those of the opposite side across the middle line.

Arching over these peduncles is a flattish band of white fibres, the *fillet*, which issues from beneath the transverse fibres of the pons, and in sections of this body can be seen lying between the deep transverse fibres and the reticular formation. If these fibres are traced upward through the pons, the outer ones will be seen to become superficial at its upper border, to pass obliquely round the superior peduncle of the cerebellum, and become lost in the quadrigeminal body, while the inner are continued upward in the crus to the cerebral hemisphere.

The *corpora geniculata* are two small, flattened, oblong masses, placed on the under and back part of each optic thalamus, and named, from their positions, *corpus geniculatum externum* and *internum*. The two bodies are separated from one another by one of the roots of the optic tract, the *brachia anterior*, from the nates.

Structure of the Cerebrum.

The *cerebrum*, like the other parts of the great nerve-centre, is composed of gray and white matter. In order to give some general idea of its construction—at all events, in part—it may be compared, for the sake of illustration, to a tree, the trunk of which divides into two main branches, and these break up into smaller branches, which finally end in twigs, to which are attached the leaves, forming an investment to the branches and covering the whole tree. The trunk is represented by the medulla oblongata as it passes through the foramen magnum; the two main branches, by the crura cerebri, which break up into smaller branches, which diverge from each other, dividing and subdividing, until they reach the surface of the hemispheres, where they terminate in single nerve-fibres, to which are attached the basal axial cylinder processes of the nerve-cells, represented by the leaves. These cells are arranged on the surface, resembling a cap covering the hemispheres, and constitute the cerebral cortex. But here the analogy ends, for in the cerebrum we have, in addition to this cortex, other masses of gray matter situated in the middle of the brain, and other white fibres besides these diverging ones which have been mentioned, and which serve either to connect together the two hemispheres of which the cerebrum consists or else serve to connect different structures in the same hemisphere.

The *white matter of the cerebrum* consists of medullated fibres, varying in size and arranged in bundles, separated by neuroglia. They may be divided into three distinct systems, according to the course which they take: 1. Diverging or peduncular fibres, which connect the hemispheres with the medulla oblongata and cord. 2. Transverse commissural fibres, which connect together the two hemi-

spheres. 3. Commissural fibres, which connect different structures in the same hemisphere.

1. The **diverging or peduncular fibres** consist of a main body, which originates in the cord and medulla oblongata, forms the longitudinal fibres of the pons, and divides into two main branches, which, diverging from each other, constitute the *crura cerebri* or *cerebral peduncles*. In the *crura cerebri*, as has been before described, the diverging fibres derived from the longitudinal fibres of the pons Varolii are arranged in two strata, which are separated by the *locus niger*, the anterior or superficial stratum forming the *crusta* of these bodies, and the posterior or deeper stratum, the *tegmentum*. The fibres derived from these two sources take a different course, and will have to be separately considered.

The fibres of the *crusta* are derived from the pyramid of the medulla, which fibres are continued upward through the pons to form the *crusta*; they are reinforced in their passage through the crus by accessory fibres derived from the central gray matter around the Sylvian aqueduct and from the *locus niger*. When they emerge from the crus (1) some of the fibres pass directly upward as radiating fibres to the gray matter of the cerebral hemisphere, forming the *corona radiata*; (2) some of the fibres pass to the internal capsule, between the nucleus caudatus and lenticularis, where they give off fibres to these ganglia and receive others from them, and then, issuing from the capsule, diverge to form a part of the *corona radiata*, passing to the cerebral cortex. The fibres which arise from the ganglia are more numerous than those which terminate in the ganglia, so that more fibres pass out of the ganglia than pass into them.

The fibres of the *tegmentum* are continuous with those longitudinal fibres of the pons which are derived from the *formatio reticularis* of the medulla, which is formed by fibres—(1) from the anterior column of the cord; (2) from the olivary body; (3) from the lateral column of the cord; and (4) from the *funiculus cuneatus* and *funiculus gracilis*. They are reinforced by fibres from the *corpora quadrigemina* and *corpora geniculata*, and from the superior peduncle of the cerebellum, and enter the optic thalamus. Some of these fibres pass through the optic thalamus, and, being augmented by other fibres arising within this body, pass out of it and spread out to form part of the *corona radiata*, especially joining the ganglion-cells of the cortex of the temporo-sphenoidal and occipital lobes; other fibres terminate in the optic thalamus.

2. The **transverse commissural fibres** connect together the two hemispheres. They include (a) the transverse fibres of the *corpus callosum*; (b) the anterior commissure; (c) the posterior commissure.

The *corpus callosum*, which has already been described, connects together the two hemispheres of the brain, forming their great transverse commissure, penetrating into the substance of the convolutions and intersecting the fibres of the *corona radiata*.

The *anterior commissure* is a round bundle of white fibres which is placed in front of the anterior *crura* of the fornix, and appears to connect the *corpora striata*. It passes outward through the *corpus striatum* on each side, and then curves backward into the substance of the temporo-sphenoidal lobe.

The *posterior commissure*, smaller than the anterior, is a flattened white band of fibres, which appears to connect together the optic thalami posteriorly. It consists of decussating fibres which come from the *tegmentum* of the *crus cerebri* on one side, and pass through the optic thalamus, across the back part of the third ventricle, to the white substance of the temporo-sphenoidal lobe of the other. Some of the fibres may also serve as commissural fibres between the optic thalami.

3. **Commissural Fibres connecting Different Structures in the Same Hemisphere.**—These fibres are of two kinds: (1) those which connect adjacent convolutions, and which are termed *arcuate* or *association fibres*; (2) those which connect more distant parts in the same hemisphere—the *longitudinal* or *collateral fibres*.

The *arcuate* or *association fibres* are situated immediately beneath the gray

substance of the cortex of the hemispheres, and connect together adjacent convolutions.

The *longitudinal* or *collateral fibres* include the following: (*a*) the uncinate fasciculus; (*b*) the fillet of the gyrus fornicatus; (*c*) the longitudinal fibres of the corpus callosum; (*d*) the tænia semicircularis; (*e*) the fornix; (*f*) the inferior longitudinal fasciculus.

(*a*) The *uncinate fasciculus* connects the convolutions of the frontal and temporo-sphenoidal lobe. It passes across the bottom of the Sylvian fissure and traverses the claustrum.

(*b*) The *fillet of the gyrus fornicatus* is a band of white matter which encircles the hemisphere in an antero-posterior direction, lying in the substance of the convolution of the corpus callosum. Commencing in front at the anterior perforated space, it passes forward and upward parallel with the rostrum, winds round the genu, runs in the convolution from before backward, immediately above the corpus callosum, turns round its posterior extremity, and is continued downward and forward in the temporo-sphenoidal lobe to again reach the perforated space. In its course it is connected with the secondary convolutions of the gyrus fornicatus by short arcuate fibres.

(*c*) The *longitudinal fibres of the corpus callosum*, or *nerves of Lancisci*, connect the anterior and posterior extremities of the gyrus fornicatus or convolution of the corpus callosum.

(*d*) The *tænia semicircularis* is a narrow whitish, semitransparent band, of medullary substance, situated in the depression between the nucleus caudatus and the optic thalamus. Anteriorly, it descends in connection with the anterior pillar of the fornix to below the level of the foramen of Monro, where it enters a mass of gray matter, the *nucleus amygdalæ*; behind, it is continued into the roof of the middle or descending horn of the lateral ventricle, and is lost near the bottom of the cornua.

(*e*) The *fornix* connects the optic thalamus with the hippocampus major and uncinate convolution. It has already been described as arising from the gray matter of the optic thalamus; it then emerges from the under surface of this body, forms the corpus albicans, where the fibres are arranged in loops, between which nerve-cells are to be found: it then passes upward into the third ventricle and joins with the fibres of the other side forming the body of the fornix; from this the posterior pillars diverge, and, entering the middle cornu of the lateral ventricle, part of its fibres are distributed to the hippocampus major, and the remainder end as the tænia hippocampi or fimbria, which is continued as a distinct piece to the *crochet* or *uncus* of the uncinate convolution.

(*f*) The *inferior longitudinal fasciculus* is a collection of fibres which connects the temporo-sphenoidal and occipital lobes, running along the outer wall of the middle and posterior cornu.

The **gray matter of the cerebrum** is disposed in three great groups: 1. The gray matter of the cerebral cortex. 2. The gray matter of the basal ganglia; that is, the great ganglia of the base of the cerebrum. 3. The gray matter which lines the internal surface of the upper part of the cerebro-spinal tube; that is, the remains of the cavity in the original vesicles from which the brain was formed, and which constitutes the central cavities of the organ.

1. The **gray matter of the cortex** (Fig. 432) invests the surface of the hemispheres and gives them external form. When vertical sections are made through it and examined microscopically, it is found to consist of five separate layers, but to this there are some exceptions. According to Meynert these exceptions are to be found: (1) in the posterior portion of the occipital lobe; (2) in the gray cortex of the hippocampus major; (3) in the wall of the fissure of Sylvius; and (4) in the olfactory bulb. The five layers in the common type are as follows: (1) The first layer is principally composed of a matrix or neuroglia, through which a few small ganglion-cells are irregularly distributed, and a nerve-fibre network. (2) The second layer consists of numerous small pyramidal cells, which have their

long axes vertical to the surface of the convolutions, and are closely aggregated together so as to completely fill the layer with a number of closely compressed cells. (3) The third layer is named by Meynert the *formation of the cornu Ammonis*, as it is made up of cells, which are the only morphological element found in this part. It consists of the same sort of pyramidal cells, arranged vertically to the surface, as was found in the preceding layer, but they are of very much larger size, and increase progressively toward the deeper parts of the layer, and they are much more widely separated from each other. This layer is the principal and broadest one of the series, and is at least twice as deep as the preceding layer. (4) The fourth layer is termed the *granular formation* by Meynert, and consists of numerous small, irregular, rarely triangular or elongated cells, which resemble the nerve-corpuscles found in the internal granule layer of the retina, and which are closely aggregated together. (5) The fifth layer is termed the *claustral formation*, and consists of a very large proportion of spindle-shaped cells, which are the peculiar elements of this layer. They are especially numerous in the inner half, and are arranged horizontally, extending parallel to the surface. They have received their name from the fact that the claustrum is made up almost entirely of an accumulation of these cells. It will be seen, therefore, that the differences in these layers depend upon the varying form and size of the cells and the closeness of their arrangement, and that the typical form of cell, and the only one which is admitted by some observers, is the pyramidal cell or nerve-corpuscle.

Character of the Pyramidal Cell or Nerve-corpuscle.—These nerve-corpuscles are destitute of a cell-wall; they present a nucleus, sometimes round or oval, sometimes angular, and give off many processes. One of these, which, in the cells arranged vertically to the surface, projects outward and is named the *process of the apex*, is strong and branched, and, according to Cleland, is continuous with the nerve-fibre network in the first or superficial layer of the cortex. Another process projects inward toward the white matter of the hemisphere and from the opposite extremity of the cell. It is termed the *process of the centre of the base*. It is more slender than the preceding and remains unbranched. It is an axis-cylinder process, and, becoming invested with a medullary sheath, constitutes a nerve-fibre, extending into the central white matter. In addition to these, lateral processes are given off, forming the *processes of the basal angle*, which can be traced for a longer or shorter distance, and break up into a network of extremely minute nerve-fibres.

Special Types of the Gray Matter of the Cortex.—The special types of gray matter of the cortex are the following: (1) On the posterior portion of the occipital lobe the gray matter consists of eight layers. This is produced by the intercalation of intermediate granule layers, similar to those forming the fourth layer of the typical cortex. (2) In the gray matter of the cortex of the hippocampus major or cornu Ammonis pyramidal cells are alone found, such as have been described in the

FIG. 432.—Gray matter of the cerebral cortex. (Meynert.)

third layer of the typical cortex. This constitutes the greater part of the structure in this situation, the fourth and fifth layers being absent and the second layer containing no cells. (3) In the wall of the Sylvian fissure the gray matter is termed the *claustrum*; it separates the white matter of the convolutions of the island of Reil from the external capsule of the corpus striatum. This presents peculiarities of structure, consisting mainly of spindle-shaped cells, such as constitute the fifth layer. (4) In the olfactory bulb, which may be regarded as a portion of the cerebral hemispheres, forming "a cap superimposed upon a conical process of the cerebrum," is another variety of structure, differing from the type of the cortex of the hemispheres. The bulb consists of both gray and white matter, and sometimes retains a central cavity lined by epithelium. The lower part is gray matter, and consists of the following layers from below upward: (1) The *olfactory nerve-layer*, consisting of a layer of non-medullated nerve-fibres derived from the nerves which supply the olfactory region. (2) The *stratum glomerulosum*, consisting of nodulated masses, containing small nuclear cells and a convoluted olfactory nerve-fibre amongst the cells. (3) The *stratum gelatinosum*, consisting of pyramidal or spindle-shaped nerve-cells and a fine network of nerve-fibre. (4) The *granular layer*, consisting of small irregular nerve-cells resembling the fourth layer of the cerebrum or the granular layer of the retina.

2. **The Gray Matter of the Basal Ganglia.**—The great ganglia of the base of the brain are the corpus striatum, the optic thalamus, the corpora quadrigemina, the corpora geniculata, and the locus niger. Only a part, however, of the gray matter of the corpora quadrigemina—that found on the periphery of this body—belongs to this group; the remainder, that contained in its centre around the Sylvian aqueduct, belongs properly to the third group, which will be discussed immediately.

The *corpus striatum* presents two distinct and separate masses, the *nucleus caudatus*, which is the intraventricular portion of the corpus striatum, and the *nucleus lenticularis*, which is the extraventricular portion. The two are separated from each other by a distinct lamina of white matter, the *internal capsule*, which also separates the nucleus lenticularis from the outer part of the optic thalamus. The gray matter of the corpus striatum is permeated by tracts of medullated nerve-fibres, some of which probably originate in it, though the actual connection of the nerve-fibres with the cells has not been demonstrated. The nerve-cells are multipolar, both large and small, the larger being principally found in the lenticular nucleus.

The *optic thalamus* is chiefly formed of gray matter, covered over by a superficial layer of white, which on the outer side separates it from the internal capsule. The gray matter is arranged in two masses, the outer and inner nuclei, partially divided by a vertical white septum. It is traversed by numerous nerve-fibres, which for the most part have no definite direction; some, however, converge and form a bundle which passes downward to form the anterior root of the fornix. It contains comparatively large nerve-cells, both multipolar and fusiform. The inner nucleus is connected across the middle line with the inner nucleus of the opposite side by the middle commissure of the third ventricle, which, however, belongs to the third group of gray matter.

The *corpora quadrigemina* consist of two distinct and separate collections of gray matter, one at or near the surface, which belongs to the basal ganglia, and one in the centre around the aqueduct of Sylvius. The former will only be considered at present. The *peripheral gray matter of the corpora quadrigemina* differs somewhat in the posterior and anterior lobes. The posterior lobes or testes are composed almost entirely of gray matter, covered over by a thin stratum of white matter, and separated from the *central gray matter* by tracts of transverse white fibres derived from, and forming part of, the fillet. The anterior lobes or nates are covered superficially by a thin stratum of white matter; beneath this is a layer of gray matter, termed the *stratum cinereum*, and consisting, as well as the gray matter of the posterior lobes, of small multipolar cells imbedded in a fine

network of nerves. Beneath this, again, is a characteristic mass of gray matter, termed the *stratum opticum*, which is made up of fine nerve-fibres, coursing in a longitudinal direction, and containing between them small masses of gray substance, consisting of small multipolar nerve-cells imbedded in gray matter. Lastly, between this body and the central gray matter around the Sylvian aqueduct is a thin lamina of white matter, derived from the fillet.

The *geniculate bodies* are continuous with the gray substance of the optic thalamus, and the external one (*corpus geniculatum externum*) is peculiar on account of its dark color, due to its cells containing pigment. It presents a laminated arrangement, and consists of alternate thick layers of gray matter and thin layers of white matter. Its cells are multipolar. The internal body (*corpus geniculatum internum*) is of lighter color, does not present a laminated arrangement, and its cells are smaller in size and fusiform in shape.

The *locus niger*, or gray matter of the crus cerebri, like the external geniculate body, is peculiar from the large amount of dark pigment-granules which are contained in its ganglion-cells, and which give to it its dark color, from which it has derived its name. Its cells are small and multipolar.

3. The **central gray matter of the cerebrum** lines the upper part of the cerebro-spinal tube, which is the remains of the cavity in the original vesicles from which the brain was formed, and is continuous with the gray matter of the floor of the fourth ventricle, and through it with the gray matter of the cord. This central gray matter is found lining the aqueduct of Sylvius, by which the third communicates with the fourth ventricle; it covers the inner wall of each optic thalamus, forming the middle or gray commissure of the third ventricle; it also lines the floor of the third ventricle; it covers behind the upper surface of the tegmentum of the crus, and in front it approaches the surface of the brain, forming the posterior perforated space and lamina cinerea. It forms also the tuber cinereum and the infundibulum, and in the lower vertebrata, especially fishes, the posterior lobe of the pituitary body. In the higher vertebrates this lobe does not present any nervous structure, being encroached upon and obliterated by an ingrowth of connective tissue and vessels.

The gray matter surrounding the Sylvian aqueduct, which has been before mentioned as the central gray matter of the corpora quadrigemina, presents some features requiring especial mention. It forms a tolerably thick layer surrounding the canal, but is thicker on the lower wall—that is, below the canal—than above. The cells, which are multipolar, are here collected into groups, and form nuclei for the origin of the third and fourth cranial nerves. The nucleus for the third and fourth consists of a column of cells of large size on either side of, and close to, the median line. In addition to these cells there are found at the periphery of the zone of gray matter surrounding the aqueduct some other, and larger, cells, sometimes single, sometimes grouped in twos or threes, or even more. They are globular, and lie in the midst of well-marked nerve-fibres, with which their processes appear to be continuous.

The Cerebellum.

The **Cerebellum**, or little brain, is that portion of the encephalon which is contained in the inferior occipital fossæ. It is situated beneath the occipital lobes of the cerebrum, from which it is separated by the tentorium. In form the cerebellum is oblong, and flattened from above downward, its great diameter being from side to side. It measures from three and a half to four inches transversely, and from two to two and a half inches from before backward, being about two inches thick in the centre, and about six lines at the circumference, which is the thinnest part. It consists of gray and white matter: the former, darker than that of the cerebrum, occupies the surface; the latter, the interior. The surface of the cerebellum is not convoluted like the cerebrum, but traversed by numerous

curved furrows or sulci, which vary in depth at different parts, and separate the laminae of which its exterior is composed.

Weight of the Cerebellum.—Its average weight in the male is 5 ozs. 4 drs. It attains its maximum weight between the twenty-fifth and fortieth year, its increase in weight after the fourteenth year being relatively greater in the female than in the male. The proportion between the cerebellum and cerebrum is, in the male, as 1 to 8 $\frac{1}{4}$; and in the female, as 1 to 8 $\frac{1}{4}$. In the infant the cerebellum is proportionately much smaller than in the adult, the relation between it and the cerebrum being, according to Chaussier, between 1 to 13 and 1 to 26; by Cruveilhier the proportion was found to be 1 to 20.

Lobes of the Cerebellum.—The cerebellum is divided into an upper and a lower portion by the great horizontal fissure, which commences in front at the pons, and passes horizontally round the free margin of the hemisphere to the middle line behind. From this primary fissure numerous secondary fissures proceed, which separate the cerebellum into lobes.

Its *upper surface* (Fig. 433) is somewhat elevated in the median line, and sloped toward its circumference; it consists of two lateral hemispheres, connected

FIG. 433.—Upper surface of the cerebellum.

together by an elevated median portion or lobe, the *superior vermiform process*. The median lobe is the fundamental part, and in some animals, as fishes and reptiles, the only part which exists, the hemispheres being additions, and attaining their maximum size in man. The hemispheres are separated, in front, by a deep notch, the *incisura cerebelli anterior*, which encircles the posterior part of the corpora quadrigemina; they are also separated by a similar notch behind, the *incisura cerebelli posterior*, in which is received the upper part of the falx cerebelli. The superior vermiform process (upper part of the median lobe of the cerebellum) extends from the notch on the anterior to that on the posterior border.

Upon the upper surface of each hemisphere there are two lobes, separated from each other by a fissure. These are the *anterior* or *square lobe*, which extends as far back as the posterior edge of the vermiform process; and the *posterior* or *semilunar lobe*, which passes from the termination of the preceding to the great horizontal fissure.

The *under surface of the cerebellum* (Fig. 434) is subdivided into two lateral hemispheres by a depression, the *vallecula* or *valley*, which extends from before backward in the middle line. These lateral hemispheres are lodged in the inferior occipital fossae; the median depression, or valley, receives the back part of the medulla oblongata, is broader in the centre than at either extremity, and has

projecting from its floor part of the median lobe of the cerebellum, called the *inferior vermiform process*.

Upon the under surface of each hemisphere there are five lobes, separated by sulci; these are, from before backward, (1) the *flocculus* or *subpeduncular lobe*, a prominent tuft situated behind and below the middle peduncle of the cerebellum; its surface is composed of gray matter, subdivided into a few small laminæ; it is sometimes called the *pneumogastric lobule*, from being situated behind the pneumogastric nerve: (2) the *amygdala* or *tonsil*, situated on either side of the great median fissure or valley, and projecting into the fourth ventricle: (3) the *digastric lobe*, situated on the outside of the tonsil, and connected in part with the pyramid: (4) the *slender lobe*, behind the digastric, and connected with the back part of the pyramid and the commissura brevis, and, more posteriorly, (5) the *inferior posterior lobe*, which also joins the commissura brevis in the valley.

FIG. 434.—Under surface of the cerebellum.

The Inferior Vermiform Process.—The parts entering into the composition of the inferior vermiform process, from behind forward, are—the *tuber valvulæ* or *commissura brevis*, a transverse lamina uniting the inferior posterior and slender lobes of the two sides; in front of this, a laminated conical projection, the *pyramid*; more anteriorly, a larger eminence, the *uvula*, which is placed between two rounded lobes, the *amygdalæ* or *tonsils*, which occupy the sides of the valley, and which is connected with them by a commissure of gray matter, indented on the surface, called the *furrowed band*. In front of the uvula is the *nodule*; it is the anterior pointed termination of the inferior vermiform process, and projects into the cavity of the fourth ventricle; it has been named by Malacarne the *laminated tubercle*. On each side of the nodule is a thin layer of white substance, attached externally to the flocculus, and internally to the nodule; these form together the *posterior medullary velum*, or commissure of the flocculus. It is usually covered in and concealed by the amygdalæ, and cannot be seen until they are drawn aside. This band is of a semilunar form on each side, its anterior margin being free and concave, its posterior attached just in front of the furrowed band. Between it and the nodule and uvula behind is a deep fossa called the *swallow's nest* (*nidus hirundinis*).

Internal Structure of the Cerebellum.—The cerebellum consists both of white and gray matter.

If a vertical section (Fig. 435) is made through either hemisphere of the cerebellum, midway between its centre and the superior vermiform process, the interior will be found to consist of a central stem of white matter, which contains in its interior a gray mass, the *corpus dentatum*. From the surface of this central stem a series of plates of medullary matter are detached, which, covered with gray matter, form the laminæ. From the anterior part of each hemisphere arise

three large processes or peduncles—superior, middle, and inferior—by which the cerebellum is connected with the rest of the encephalon.

The **white matter** includes two varieties of nerve-matter: (1) the *peduncular fibres*, which are directly continuous with the fibres of the peduncles of the cerebellum; (2) the fibres (*fibræ propriæ*) proper to the cerebellum itself.

The *peduncles of the cerebellum*—superior, middle, and inferior—serve to connect it with the rest of the encephalon.

The *superior peduncles* (*processus e cerebello ad testes*) arise from the middle of the white matter of the cerebral hemispheres; they run beneath the testes of the corpora quadrigemina, and, emerging at its posterior border, pass outward and backward to the cerebellum. Each peduncle forms the upper part of the lateral boundary of the fourth ventricle, and is connected with its fellow of the opposite side by the *valve of Vieussens*. Beneath the corpora quadrigemina the innermost fibres of each peduncle decussate with each other, so that some fibres from the one half of the cerebrum are continued into the other half of the cerebellum. Upon

FIG. 435.—Vertical section of the cerebellum.

entering the cerebellum the fibres of this peduncle pass to a great extent into the interior of the corpus dentatum, though some wind round it and reach the gray cortical matter, especially on its inferior surface.

The *valve of Vieussens*, or *superior medullary velum*, is a thin translucent lamina of white matter, marked superficially by a few transverse streaks of gray substance, stretched between the two *processus e cerebello ad testes*; it forms part of the roof of the fourth ventricle. It is narrow in front, where it is connected with the testes, and broader behind, at its connection with the vermiform process of the cerebellum. A slight elevated ridge, the *frœnulum*, descends upon the upper part of the valve from the corpora quadrigemina, and on either side of it may be seen the fourth nerve, which is connected with its fellow of the opposite side by a transverse band of fibres forming a partial decussation. Its lower half is covered by a thin, transversely-grooved lobule of gray matter prolonged from the anterior border of the cerebellum; this is called the *lingula*.

The *middle peduncles* (*processus ad pontem*), the largest of the three, connect together the two hemispheres of the cerebellum, forming their great transverse commissure. They consist of a mass of curved fibres, which arise in the gray matter of the foliated cortex of the hemispheres of the cerebellum, and pass across the pons Varolii, forming its transverse fibres.

The *inferior peduncles* (*processus ad medullam*) connect the cerebellum with the medulla oblongata. As the restiform bodies they pass upward and outward,

forming part of the lateral wall of the fourth ventricle; entering the cerebellum, they end in the gray cortex of the upper surface of this organ.

The *fibræ propriae* of the cerebellum are of two kinds: (1) *commissural fibres*, which cross the middle line to connect the opposite halves of the hemispheres, some at the anterior part, and others at the posterior part of the vermiform process; (2) *arcuate* or *association fibres*, which connect one lamina with another, arching across the fissures between the laminae.

The **gray matter of the cerebellum** is found in two situations: (1) on the surface, forming the cortex; (2) as independent masses in the interior.

1. The *gray matter of the cortex* presents a characteristic foliated appearance,

FIG. 436.—Vertical section through the gray matter of the human cerebellum. Magnified about 100 diameters. (Klein and Noble Smith.)

due to the series of laminae which are given off from the central white matter; these laminae give off secondary laminae which are covered with gray matter. This arrangement gives to the cut surface of the organ a foliated appearance, to which the name *arbor vitae* has been applied (Fig. 435). Externally the cortex is covered by pia mater, and internally is the medullary centre, consisting mainly of nerve-fibres.

Microscopical Appearance of the Cortex.—The cortex presents a remarkable structure, consisting of two distinct layers—viz. an external gray or cellular layer, and an internal rust-colored granular layer. Between the two layers, or rather

situated in the deepest part of the gray or cellular layer, is an incomplete stratum of the characteristic cells of the cerebellum, the *corpuscles of Purkinje*.

The *external gray or cellular layer* (Fig. 436) consists of a transparent tissue-like neuroglia containing fibres and cells. The fibres are delicate fibrillæ running at right angles to the surface, and many of them connected with the processes of the large nerve-cells immediately below; others are delicate supporting connective-tissue-like fibres, which spread out into a broad base against the inner surface of the pia mater.

The cells are granular bodies, some very small, and probably belonging to the neuroglia; others, according to Lockhart Clarke, connected with the processes of the corpuscles of Purkinje which lie immediately beneath.

The *corpuscles of Purkinje* (Fig. 436) are flask-shaped cells in the deepest part of the external gray or cellular layer, resting against the internal rust-colored layer. From their under surface a slight slender process arises, which passes through the internal layer, and becomes continuous with the axial cylinder of a medullated nerve-fibre in the medullary substance beneath. From the other extremity two peripheral processes are given off, which branch in an antler-like manner in the external layer, some of the finer processes becoming connected with the cells in this layer.

The *internal or rust-colored layer* (Fig. 436) is characterized by containing multitudes of granular-looking bodies imbedded in a gelatinous matrix. They are minute stellate cells, consisting of a well-defined nucleus with a thin protoplasmic envelope. Between the cells is a fine nerve-network, with which the processes of the cells are supposed to be continuous.

FIG. 437.—A corpuscle of Purkinje, with its dichotomously branched processes.

2. The *independent centres of gray matter in the cerebellum* are—(1) the *corpus dentatum*; (2) the *roof nuclei of Stilling*.

The *corpus dentatum*, or *ganglion of the cerebellum*, is situated a little to the inner side of the centre of the stem of white matter. It consists of an open bag or capsule of gray matter, the section of which presents a gray dentated outline, open at its anterior part. It is surrounded by white fibres; white fibres are also contained in its interior, which issue from it to join the superior peduncles.

The *roof nuclei of Stilling* are two small gray masses, situated at the anterior end of the superior vermiciform process, and projecting into the valve of Vieussens, so as to assist in the formation of the roof of the fourth ventricle. These can only be seen in microscopic preparations.

The Fourth Ventricle (Fig. 430).

The **Fourth Ventricle**, or *ventricle of the cerebellum*, is the space between the posterior surface of the medulla oblongata and pons in front and the cerebellum behind. It is lozenge or diamond-shaped; that is to say, it is composed of two triangles, with their bases opposed to each other. The lower triangle is formed by the divergence of the funiculi graciles and the restiform bodies of the medulla oblongata on either side. These columns pass upward and outward at an acute angle to the lateral hemispheres of the cerebellum, leaving by their divergence a triangular space which forms the lower half of the fourth ventricle. In like manner the upper triangle is formed by the divergence of the superior peduncles (*processus e cerebello ad testes*) of the cerebellum. These crura as they emerge from the corpora quadrigemina are in contact by their lateral margins, but they gradually diverge, passing downward, backward, and outward, to reach the cerebellum, thus enclosing a triangular space which forms the upper half of the fourth

ventricle. This cavity is therefore bounded laterally by the *processus e cerebello ad testes* above, and by the diverging *funiculi graciles* and *restiform bodies* below.

It presents four angles. The upper angle reaches as high as the upper border of the pons; it presents the lower opening of the aqueduct of Sylvius, by which this ventricle communicates with the third ventricle. The lower angle is on a level with the lower border of the olivary body, and presents a minute opening, the aperture of the central canal of the spinal cord. At its lateral angles the fourth ventricle is extended for a short distance between the side of the medulla and the cerebellum, where these two structures come in contact.

The *roof* is arched, and is formed in the upper triangle by part of the superior peduncles of the cerebellum and the valve of Vieussens (superior medullary velum), a lamina of white matter streaked with gray, which bridges across from one superior peduncle to the other. The roof of the lower half is formed by a reflection of pia mater passing from the under surface of the inferior vermiform process of the cerebellum to the lower part of the medulla oblongata. Above this is the inferior vermiform process itself. This pia-matral covering is lined on its under or ventricular surface by a layer of epithelium, which is continuous with that lining the sides and base of the cavity, and is perforated by a hole, the *foramen of Majendie*, by which the cavity of the ventricle communicates with the subarachnoid space.

The *floor* is formed by the posterior surface of the medulla oblongata and pons. In the median line is seen a fissure which gradually becomes obliterated above and terminates below, near the point of the *calamus scriptorius*, in a somewhat cleft-like space, the ventricle of Arantius, which opens by a minute hole into the central canal of the spinal cord. From the resemblance that there is in the diverging lower boundaries of the space and the central fissure to the nib of a writing-pen the lower triangle has been named the *calamus scriptorius*. On each side of the median fissure are two spindle-shaped longitudinal eminences, the *fasciculi teretes*; they extend the entire length of the floor, being indistinct below and of a grayish color, but well marked and whiter, above. Each eminence consists of a portion of the base of the anterior cornu of gray matter of the medulla, which comes to the surface of the floor of the fourth ventricle, where the central canal of the spinal cord opens out into this cavity. External to this eminence there is a slight groove which terminates below in a little fossa, called the *fovea inferior*; and in the same groove, opposite the widest part of the ventricle, there is a second depression or fossa, called the *fovea superior*. Above the superior fovea, and external to the *fasciculi teretes*, is a small eminence of dark-gray substance, which presents a bluish tint through the thin stratum covering it; this is called the *locus ceruleus*; and a thin streak of the same color, continuing up from this on either side of the *fasciculi teretes* as far as the top of the ventricle is called the *tania violacea*. The lower part of the floor of the ventricle is crossed by several white transverse lines, *lineæ transversæ* or *auditory striæ*; they emerge from the posterior median fissure and enter the roots of origin of the auditory nerve.

The *lining membrane of the fourth ventricle* is continuous with that of the third through the aqueduct of Sylvius, and its cavity communicates below with the subarachnoid space of the brain and cord through an aperture in the layer of pia mater extending between the cerebellum and medulla oblongata. Laterally, this membrane is reflected outward a short distance between the cerebellum and medulla.

The *choroid plexuses* of the fourth ventricle are two in number: they are delicate vascular fringes which project into the ventricle on each side, passing from the point of the inferior vermiform process to the outer margin of the restiform bodies.

The *gray matter* in the floor of the ventricle consists of a tolerably thick stratum, continuous below with the gray commissure of the cord, and extending up as high as the aqueduct of Sylvius, and, in addition, of some special deposits connected with the deep origin of certain of the cranial nerves.

These special deposits produce little elevations on the floor of the ventricle. The nucleus of the fifth is placed the highest; the deep origin of the larger or sensory root is from a nucleus on a level with the middle of the superior peduncle of the cerebellum, just internal to the margin of the ventricle; the deep origin of the smaller root is from a nucleus internal to the sensory root, and just external to the fasciculus teres on the floor of the ventricle.

The origin of the sixth is a little lower than the motor root of the fifth, and close to the median line beneath the anterior portion of the fasciculus teres.

The deep origin of the seventh, or facial, is a little below and external to the nucleus of the sixth, above the level of the auditory striæ.

The deep origin of the eighth, or auditory, is twofold: one from a prominence, the *auditory tubercle*, on the outer side of the inferior fovea; the other is situated at the lateral angle of the ventricle. Into this latter run the auditory striæ.

The deep origin of the ninth, or glosso-pharyngeal, is from a nucleus of gray matter at the lower part of the ventricle, beneath the inferior fovea, below the inner nucleus of the eighth or auditory nerve.

The deep origin of the tenth, or pneumogastric, is from a nucleus of gray matter at the lower part of the ventricle, below and continuous with the nucleus of origin of the ninth or glosso-pharyngeal nerve.

The deep origin of the eleventh or accessory portion of the spinal accessory is from a nucleus of gray matter at the back of the medulla, extending from the level of the top of the calamus scriptorius as far down as the intermedio-lateral tract of the spinal cord.

The deep origin of the twelfth, or hypoglossal, is from a nucleus of gray matter on the floor of the ventricle, on either side of the middle line, extending from the level of the auditory striæ to the lowest point of the ventricle of Arantius.

THE CRANIAL NERVES.

The cranial nerves arise from some part of the cerebro-spinal centre, and are transmitted through foramina in the base of the cranium. They have been named numerically, according to the order in which they pass through the dura mater lining the base of the skull. Other names are also given to them, derived from the parts to which they are distributed or from their functions. Taken in their order, from before backward, they are as follows:

- | | |
|------------------------------|----------------------------------|
| 1st. Olfactory. | 7th. Facial (Portio dura). |
| 2d. Optic. | 8th. Auditory (Portio mollis). |
| 3d. Motor oculi. | 9th. Glosso-pharyngeal. |
| 4th. Pathetic. | 10th. Pneumogastric (Par vagum). |
| 5th. Trifacial (Trigeminus). | 11th. Spinal accessory. |

All the cranial nerves are connected to some part of the surface of the brain. This is termed their *superficial* or *apparent origin*. But their fibres may, in all cases, be traced deeply into the substance of the brain to some special centre of gray matter, termed a *nucleus*. This is called their *deep* or *real origin*. The nerves, after emerging from the brain at their apparent origin, pass through foramina or tubular prolongations in the dura mater, leave the skull through foramina in its base, and pass to their final distribution.

First Nerve (Fig. 423, page 727).

The **First Cranial** or **Olfactory Nerves**, the special nerves of the sense of smell, are about twenty in number. They are given off from the under surface of the olfactory bulb, an oval mass of a grayish color, which rests on the cribriform plate of the ethmoid bone, and forms the anterior expanded extremity of a slender process of brain-substance, named the *olfactory tract* (see page 728). The olfactory tract, when traced backward, divides into three slips or roots at its base. The middle root is attached to the under surface of the frontal lobe, just in front of

the anterior perforated space. The external root passes outward, round the anterior perforated space, across the fissure of Sylvius to the temporo-sphenoidal lobe. The internal root passes inward, and joins the lower end of the corpus callosum.

These three roots unite and form a flat band, narrower in the middle than at either extremity, and of a somewhat prismoid form on section. It is soft in texture and contains a considerable amount of gray matter in its substance. As it passes forward it is contained in a deep sulcus, the *olfactory sulcus*, between two convolutions, lying on the under surface of the frontal lobe, on either side of the longitudinal fissure, and is retained in position by the arachnoid membrane, which covers it. On reaching the cribriform plate of the ethmoid bone it expands into the *olfactory bulb*. From the under part of this bulb are given off the olfactory nerves, which pass through the cribriform foramina and are distributed to the mucous membrane of the nose. Each nerve is surrounded by a tubular prolongation from the dura mater and pia mater; the former being lost on the periosteum lining the nose; the latter, in the neurilemma of the nerve. The nerves, as they enter the nares, are divisible into three groups: an inner group, larger than those on the outer wall, spread out over the upper third of the septum; a middle set, confined to the roof of the nose; and an outer set, which are distributed over the superior and middle turbinated bones and the surface of the ethmoid in front of them. As the filaments descend they unite in a plexiform network, and are believed by most observers to terminate in the *cells of Schultze*.

The olfactory differs in structure from other nerves in being composed exclusively of non-medullated fibres. They are deficient in the white substance of Schwann, and consist of axis-cylinders, with a distinct nucleated sheath, in which there are, however, fewer nuclei than in ordinary non-medullated fibres.

Surgical Anatomy.—In severe injuries to the head the olfactory bulb may become separated from the olfactory nerves, thus producing loss of the sense of smelling (*anosmia*), and with this a considerable loss in the sense of taste, as much of the perfection of the sense of taste is due to the sapid substances being also odorous and simultaneously exciting the sense of smell.

Second Nerve (Fig. 438).

The **Second or Optic Nerve**, the special nerve of the sense of sight, is distributed exclusively to the eyeball. The nerves of opposite sides are connected together at the commissure, and from the back of the commissure they may be traced to the brain, under the name of the *optic tracts*.

The *optic tract*, at its connection with the brain, is divided into two bands. One of these arises from the *stratum opticum* of the corpora quadrigemina, and emerges from the nates of this body as the anterior brachium, and passes obliquely outward between the inner and outer geniculate bodies; the second arises from the optic thalamus, and passes through the inner geniculate body, from which it derives fibres, and joins with the other band to form the optic tract. From this origin the tract winds obliquely across the under surface of the crus cerebri in the form of a flattened band, destitute of neurilemma and attached to the crus by its anterior margin. It then assumes a cylindrical form, and, as it passes forward is connected with the *tuber cinereum* and *lamina cinerea*, from both of which it receives fibres. It finally joins with the tract of the opposite side to form the *optic commissure*.

FIG. 438.—The left optic nerve and optic tracts.

The *commissure* or *chiasma*, somewhat quadrilateral in form, rests upon the optic groove of the sphenoid bone, being bounded, above, by the lamina cinerea ;

FIG. 439.—Course of the fibres in the optic commissure.

behind, by the tuber cinereum ; on either side, by the anterior perforated space. Within the commissure the optic nerves of the two sides undergo a partial decussation. The fibres which form the inner margin of each tract are continued across from one to the other side of the brain, and have no connection with the optic nerves. These may be regarded as commissural fibres (*intercerebral*) between the thalami of opposite sides. Some fibres are continued across the anterior

border of the chiasma, and connect the optic nerves of the two sides, having no relation with the optic tracts.¹ They may be regarded as commissural fibres between the two retinae (*inter-retinal fibres*). The outer fibres of each tract are continued into the optic nerve of the same side. The central fibres of each tract are continued into the optic nerve of the opposite side, decussating in the commissure with similar fibres of the opposite tract.²

The *optic nerves* arise from the fore part of the commissure, and, diverging from one another, become rounded in form and firm in texture, and are enclosed in a sheath derived from the arachnoid. As each nerve passes through the corresponding optic foramen it receives a sheath from the dura mater ; and as it enters the orbit this sheath subdivides into two layers, one of which becomes continuous with the periosteum of the orbit ; the other forms the proper sheath of the nerve and surrounds it as far as the sclerotic. The nerve passes through the cavity of the orbit, pierces the sclerotic and choroid coats at the back part of the eyeball, a little to the nasal side of its centre, and expands into the retina. Arnold describes a communication between the optic nerve in the orbit and the ascending branches of Meckel's ganglion. A small artery, the *arteria centralis retinae*, perforates the optic nerve a little behind the globe, and runs along its interior in a tubular canal of fibrous tissue. It supplies the inner surface of the retina, and is accompanied by corresponding veins.

Surgical Anatomy.—The optic nerve is peculiarly liable to become the seat of neuritis or undergo atrophy in affections of the central nervous system, and, as a rule, the pathological relationship between the two affections is exceedingly difficult to trace. There are, however, certain points in connection with the anatomy of this nerve which tend to throw light upon the frequent association of these affections with intracranial disease : (1) From its mode of development (see page 123) and from its structure the optic nerve must be regarded as a prolongation of the brain-substance, rather than as an ordinary cerebro-spinal nerve. (2) As it passes from the brain it receives sheaths from the three cerebral membranes—a perineural sheath from the pia mater, an intermediate sheath from the arachnoid, and an outer sheath from the dura mater, which is also connected with the periosteum as it passes through the optic foramen. These sheaths are separated from each other by spaces which communicate with the subdural and subarachnoid spaces respectively. The innermost or perineural sheath sends a process around the *arteria centralis retinae* into the interior of the nerve, and enters intimately into the structure of the nerve. Thus inflammatory affections of the meninges or of the brain may readily extend themselves along these spaces or along the interstitial connective tissue in the nerve.

The course of the fibres in the optic commissure has an important pathological bearing, and has been the subject of much controversy. Microscopic examination, experiments, and pathology all seem to point to the fact that there is a partial decussation of the fibres, each tract supplying the corresponding half of each eye, so that the right tract supplies the right half of each eye, and the left tract the left half of each eye. At the same time, Charcot believes—and his view has met with general acceptance—that the fibres which do not decussate at the optic commissure have already decussated in the corpora quadrigemina, so that lesion of the cerebral centre of one side causes complete blindness of the opposite eye, because both sets of decussating fibres are destroyed. Whereas should one tract—say the right—be destroyed by disease, there will be blindness of the right half of both retinae.

An antero-posterior section through the commissure would divide the decussating fibres, and would therefore produce blindness of the inner half of each eye ; while a section at the

¹ The presence of these fibres has been doubted by some observers, but they have been recently asserted to exist by Stilling.

² A specimen of congenital absence of the optic commissure is to be found in the Museum of the Westminster Hospital. (See also Henle, *Nervenchke*, p. 393, ed. 2.)

margin of the side of the optic commissure would produce blindness of the external half of the retina of the same side.

The optic nerve may also be affected in injuries or diseases involving the orbit, in fractures of the anterior fossa of the base of the skull, in tumors of the orbit itself, or those invading this cavity from neighboring parts.

Third Nerve (Figs. 440, 441, 442).

The **Third or Motor Oculi Nerve** supplies all the muscles of the orbit, except the Superior oblique and External rectus; it also sends motor filaments to the iris and the ciliary muscle. It is a rather large nerve, of rounded form and firm texture. Its apparent origin is from the inner surface of the crus cerebri, immediately in front of the pons Varolii.

The *deep origin* may be traced through the locus niger and tegmentum of the crus to a nucleus situated on either side of the median line beneath the floor of the aqueduct of Sylvius. On emerging from the brain the nerve is invested with a sheath of pia mater, and enclosed in a prolongation from the arachnoid. It then pierces the dura mater in front of and external to the posterior clinoid process, passing between the two processes from the free and attached borders of the tentorium, which are prolonged forward to be connected with the anterior and posterior clinoid processes of the sphenoid bone. It passes along the outer wall of the cavernous sinus, above the other orbital nerves, receiving in its course one or two filaments from the cavernous plexus of the sympathetic. It then divides into two branches, which enter the orbit through the sphenoidal fissure between the two heads of the External rectus muscle. On passing through the fissure the nerve is placed below the fourth and the frontal and lachrymal branches of the ophthalmic nerve, and has passing between its two divisions the nasal nerve.

The *superior division*, the smaller, passes inward over the optic nerve, and supplies the Superior rectus and Levator palpebræ. It occasionally communicates with the ganglionic branch of the nasal nerve.

The *inferior division*, the larger, divides into three branches. One passes beneath the optic nerve to the Internal rectus; another, to the Inferior rectus; and the third, the largest of the three, passes forward between the Inferior and External recti to the Inferior oblique. From this latter a short, thick branch is given off to the lower part of the lenticular ganglion, which forms its inferior root. It also gives off one or two filaments to the Inferior rectus. All these branches enter the muscles on their ocular surface.

Surgical Anatomy.—Paralysis of the third nerve may be the result of many causes: as cerebral disease; conditions causing pressure on the cavernous sinus; periostitis of the bones

FIG. 440.—Nerves of the orbit. Seen from above.

entering into the formation of the sphenoidal fissure. It results, when complete, in (1) ptosis, or drooping of the upper eyelid, in consequence of the Levator palpebræ being paralyzed; (2) external strabismus, on account of the unopposed action of the External rectus muscle, which is not supplied by the third nerve, and is not therefore paralyzed; (3) dilatation of the pupil, because the sphincter fibres of the iris are paralyzed; (4) loss of power of accommodation, as the sphincter pupillæ, the ciliary muscle, and the Internal rectus are paralyzed; (5) slight prominence of the eyeball, from the compressing action of the Superior oblique, which is not paralyzed. Occasionally paralysis may affect only a part of the nerve; that is to say, there may be, for example, a dilated and fixed pupil, with ptosis, but no other signs. Irritation of the nerve causes spasm of one or other of the muscles supplied by it; thus, there may be internal strabismus from spasm of the Internal rectus; accommodation for near objects only from spasm of the ciliary muscle, or myosis, contraction of the pupil, from irritation of the sphincter of the pupil.

Fourth Nerve (Fig. 440).

The **Fourth or Trochlear Nerve** (*pathetic*), the smallest of the cranial nerves, supplies the Superior oblique muscle. Its *apparent origin*, at the base of the brain, is on the outer side of the crus cerebri, just in front of the pons Varolii, but the fibres can be traced backward behind the corpora quadrigemina to the valve of Vieussens, on the upper surface of which the two nerves decussate. Its *deep origin* may be traced to the nucleus in the floor of the aqueduct of Sylvius

FIG. 441.—Plan of the motor oculi nerve. (After Flower.)

immediately below that of the third nerve, with which it is continuous. The nerve winds round the outer side of the crus cerebri, immediately above the pons Varolii, pierces the dura mater in the free border of the tentorium cerebelli, just behind, and external to, the posterior clinoid process, and passes forward in the outer wall of the cavernous sinus, between the third nerve and the ophthalmic division of the fifth. It crosses the third nerve, and enters the orbit through the sphenoidal fissure. It now becomes the highest of all the nerves, lying at the inner extremity of the fissure internal to the frontal nerve. In the orbit it passes inward above the origin of the Levator palpebræ, and finally enters the orbital surface of the Superior oblique muscle.

In the outer wall of the cavernous sinus this nerve is not unfrequently blended with the ophthalmic division of the fifth. *Branches of Communication.*—In the outer wall of the cavernous sinus it receives some filaments from the cavernous plexus of the sympathetic. In the sphenoidal fissure it occasionally gives off a branch to assist in the formation of the lachrymal nerve. *Branches of Distribution.*—It gives off a recurrent branch, which passes backward between the layers of the tentorium, dividing into two or three filaments which may be traced as far back as the wall of the lateral sinus.

Surgical Anatomy.—The fourth nerve when paralyzed causes loss of function in the Superior oblique, so that the patient is unable to turn his eye downward and outward. Should the patient attempt to do this, the eye on the affected side is twisted inward, producing diplopia or double vision. Accordingly, it is said that the first symptom of this disease which presents itself is giddiness when going down hill or in descending stairs, owing to the double vision induced by the patient looking at his steps while descending.

Fifth Nerve.

The **Fifth** or **Trifacial Nerve** (*trigeminus*) is the largest cranial nerve. It resembles a spinal nerve (1) in arising by two roots; (2) in having a ganglion developed on its posterior root; and (3) in its function, since it is a compound nerve. It is the great sensory nerve of the head and face and the motor nerve of the muscles of mastication. Its upper two divisions are entirely sensory; the third division is partly sensory and partly motor. It arises by two roots: of these the anterior is the smaller, and is the motor root; the posterior, the larger and sensory. Its *superficial origin* is from the side of the pons Varolii, nearer to the upper than the lower border. The smaller root consists of three or four bundles; the larger root consists of numerous bundles of fibres, varying in number from seventy to a hundred. The two roots are separated from one another by a few of the transverse fibres of the pons. The *deep origin* of the larger or sensory root is from a nucleus on a level with the middle of the superior peduncle of the cerebellum, just internal to the margin of the fourth ventricle. The *deep origin* of the smaller or motor root is from a nucleus internal to the sensory root, and just external to the fasciculus teres on the floor of the fourth ventricle. The two roots of the nerve pass forward through an oval opening in the dura mater, on the superior border of the petrous portion of the temporal bone, above the internal auditory meatus; they then run between the bone and the dura mater to the apex of the petrous portion of the temporal bone, where the fibres of the sensory root form a large, semilunar ganglion (*Gasserian*), while the motor root passes beneath the ganglion without having any connection with it, and joins outside the cranium with one of the trunks derived from it.

The *Gasserian* or *semilunar ganglion*¹ is lodged in a depression near the apex of the petrous portion of the temporal bone. It is of somewhat crescentic form, with its convexity turned forward. Its upper surface is intimately adherent to the dura mater. Besides the small or motor root, the large superficial petrosal nerve lies underneath the ganglion.

Branches of Communication.—This ganglion receives, on its *inner side*, filaments from the carotid plexus of the sympathetic. *Branches of Distribution.*—It gives off minute branches to the tentorium cerebelli and the dura mater in the middle fossa of the cranium. From its *anterior border*, which is directed forward and outward, three large branches proceed—the *ophthalmic*, *superior maxillary*, and *inferior maxillary*. The ophthalmic and superior maxillary consist exclusively of fibres derived from the larger root and ganglion, and are solely nerves of common sensation. The third division, or inferior maxillary, is joined outside the cranium by the motor root. This, therefore, strictly speaking, is the only portion of the fifth nerve which can be said to resemble a spinal nerve.

Ophthalmic Nerve (Figs. 440, 442, 443).

The **Ophthalmic**, or first division of the fifth, is a sensory nerve. It supplies the eyeball, the lachrymal gland, the mucous lining of the eye and nasal fossæ, and the integument of the eyebrow, forehead, and nose. It is the smallest of the three divisions of the fifth, arising from the upper part of the Gasserian

¹ A Viennese anatomist, Raimund Balthasar Hirsch (1765), was the first who recognized the ganglionic nature of the swelling on the sensory root of the fifth nerve, and called it, in honor of his otherwise unknown teacher, Jön. Laur. Gasser, the "Ganglion Gasseri." Julius Casserius, whose name is given to the musculo-cutaneous nerve of the arm, was professor at Padua, 1545-1605. (See Hyrtl, *Lehrbuch der Anatomie*, p. 895 and p. 55.)

ganglion. It is a short, flattened band, about an inch in length, which passes forward along the outer wall of the cavernous sinus, below the other nerves, and just before entering the orbit, through the sphenoidal fissure, divides into three branches—*lachrymal*, *frontal*, and *nasal*.

Branches of Communication.—The ophthalmic nerve is joined by filaments from the cavernous plexus of the sympathetic, communicates with the third and sixth nerves, and is not unfrequently joined with the fourth.

Branches of Distribution.—It gives off recurrent filaments which pass between the layers of the tentorium along with a branch from the fourth nerve, and then divides into

Lachrymal.

Frontal.

Nasal.

The **Lachrymal** is the smallest of the three branches of the ophthalmic. Not unfrequently it arises by two filaments, one from the ophthalmic, the other from the fourth. It passes forward in a separate tube of dura mater and enters the

FIG. 442.—Nerves of the orbit and ophthalmic ganglion. Side view.

orbit through the narrowest part of the sphenoidal fissure. In the orbit it runs along the upper border of the External rectus muscle with the lachrymal artery, and sends off a recurrent branch which joins the orbital branch of the superior maxillary nerve, and occasionally takes the place of the temporal branch of this nerve, which is then absent. Within the lachrymal gland it gives off several filaments, which supply the gland and the conjunctiva. Finally, it pierces the tarsal ligaments, and terminates in the integument of the upper eyelid, joining with filaments of the facial nerve.

The **Frontal** is the largest division of the ophthalmic, and may be regarded, both from its size and direction, as the continuation of the nerve. It enters the orbit above the muscles through the highest and broadest part of the sphenoidal fissure, and runs forward along the middle line, between the Levator palpebræ and the periosteum. Midway between the apex and base of the orbit it divides into two branches, supratrochlear and supra-orbital.

The *supratrochlear branch*, the smaller of the two, passes inward above the pulley of the Superior oblique muscle, and gives off a descending filament, which joins with the infratrochlear branch of the nasal nerve. It then escapes from the orbit between the pulley of the Superior oblique and the supra-orbital foramen, curves up on to the forehead close to the bone, and ascends beneath the Corrugator

supercilii and Occipito-frontalis muscles, and supplies the integument of the lower part of the forehead on either side of the middle line.

The *supra-orbital branch* passes forward through the supra-orbital foramen, and gives off, in this situation, palpebral filaments to the upper eyelid. It then ascends upon the forehead, and terminates in cutaneous and pericranial branches. The *cutaneous branches*, two in number, an inner and an outer, supply the integument of the cranium as far back as the occiput. They are at first situated beneath the Occipito-frontalis, the inner branch perforating the frontal portion of the muscle, the outer branch its tendinous aponeurosis. The *pericranial branches* are distributed to the pericranium over the frontal and parietal bones.

The **Nasal nerve** is intermediate in size between the frontal and lachrymal, and more deeply placed than the other branches of the ophthalmic. It enters the orbit between the two heads of the External rectus, and passes obliquely inward across the optic nerve, beneath the Levator palpebrae and Superior rectus muscles, to the inner wall of the orbit, where it enters the anterior ethmoidal foramen, immediately below the Superior oblique. It then enters the cavity of the cranium, traverses a shallow groove on the front of the cribriform plate of the ethmoid bone, and passes down, through the slit by the side of the crista galli, into the nose, where it divides into two branches, an internal and an external. The *internal branch* supplies the mucous membrane near the fore part of the septum of the nose. The *external branch* descends in a groove on the inner surface of the nasal bone, and supplies a few filaments to the mucous membrane covering the fore part of the outer wall of the nares as far as the inferior spongy bone; it then leaves the cavity of the nose, between the lower border of the nasal bone and the upper lateral cartilage of the nose, and, passing down beneath the Compressor nasi, supplies the integument of the ala and the tip of the nose, joining with the facial nerve.

The branches of the nasal nerve are the *ganglionic*, *ciliary*, and *infratrochlear*.

The *ganglionic* is a slender branch, about half an inch in length, which usually arises from the nasal, between the two heads of the External rectus. It passes forward on the outer side of the optic nerve, and enters the superior and posterior angle of the ciliary ganglion, forming its superior or long root. It is sometimes joined by a filament from the cavernous plexus of the sympathetic or from the superior division of the third nerve.

The *long ciliary nerves*, two or three in number, are given off from the nasal as it crosses the optic nerve. They join the short ciliary nerves from the ciliary ganglion, pierce the posterior part of the sclerotic, and, running forward between it and the choroid, are distributed to the ciliary muscles, iris, and cornea.

The *infratrochlear branch* is given off just before the nasal nerve passes through the anterior ethmoidal foramen. It runs forward along the upper border of the Internal rectus, and is joined, beneath the pulley of the Superior oblique, by a filament from the supratrochlear nerve. It then passes to the inner angle of the eye, and supplies the integument of the eyelids and side of the nose, the conjunctiva, lachrymal sac, and caruncula lachrymalis.

Ophthalmic Ganglion (Figs. 442, 443).

Connected with the three divisions of the fifth nerve are four small ganglia. With the first division is connected the *ophthalmic ganglion*; with the second division, the *spheno-palatine* or *Meckel's ganglion*; and with the third, the *otic* and *submaxillary ganglia*. All the four receive sensory filaments from the fifth, and motor and sympathetic filaments from various sources; these filaments are called the *roots of the ganglia*.

The **Ophthalmic, Lenticular, or Ciliary Ganglion** is a small, quadrangular, flattened ganglion, of a reddish-gray color, and about the size of a pin's head, situated at the back part of the orbit between the optic nerve and the External rectus muscle, lying generally on the outer side of the ophthalmic artery. It is enclosed in a quantity of loose fat, which makes its dissection somewhat difficult.

FIG. 443.—Plan of the fifth cranial nerve. (After Flower.)

Its branches of communication, or roots, are three, all of which enter its posterior border. One, the long or sensory root, is derived from the nasal branch

of the ophthalmic and joins its superior angle. The second, the short or motor root, is a short, thick nerve, occasionally divided into two parts, which is derived from the branch of the third nerve to the Inferior oblique muscle, and is connected with the inferior angle of the ganglion. The third, the sympathetic root, is a slender filament from the cavernous plexus of the sympathetic. This is frequently blended with the long root, though it sometimes passes to the ganglion separately. According to Tiedemann, this ganglion receives a filament of communication from the sphenopalatine ganglion.

Its *branches of distribution* are the short ciliary nerves. These are delicate filaments, from six to ten in number, which arise from the fore part of the ganglion in two bundles, connected with its superior and inferior angles; the lower bundle is the larger. They run forward with the ciliary arteries in a wavy course, one set above and the other below the optic nerve, and are joined by the long ciliary nerves from the nasal. They pierce the sclerotic at the back part of the globe, pass forward in delicate grooves on its inner surface, and are distributed to the ciliary muscle, iris, and cornea. Tiedemann has described one small branch as penetrating the optic nerve with the arteria centralis retinae.

Superior Maxillary Nerve (Fig. 444).

The **Superior Maxillary**, or second division of the fifth, is a sensory nerve. It is intermediate, both in position and size, between the ophthalmic and inferior maxillary. It commences at the middle of the Gasserian ganglion as a flattened plexiform band, and passes forward through the foramen rotundum, where it becomes more cylindrical in form and firmer in texture. It then crosses the sphenomaxillary fossa, enters the orbit through the sphenomaxillary fissure, traverses the infra-orbital canal in the floor of the orbit, and appears upon the face at the infra-orbital foramen.¹ At its termination the nerve lies beneath the Levator labii superioris muscle, and divides into a leash of branches, which spread out upon the side of the nose, the lower eyelid, and upper lip, joining with filaments of the facial nerve.

Branches of Distribution.—The branches of this nerve may be divided into four groups: 1. Those given off in the cranium. 2. Those given off in the sphenomaxillary fossa. 3. Those in the infra-orbital canal. 4. Those on the face.

In the cranium . . .	Meningeal.
Spheno-maxillary fossa	{ Orbital or temporo-malar.
	{ Spheno-palatine.
	{ Posterior superior dental.
Infra-orbital canal .	{ Middle superior dental.
	{ Anterior superior dental.
	{ Palpebral.
On the face . . .	{ Nasal.
	{ Labial.

The **meningeal branch** is given off directly after its origin from the Gasserian ganglion, and supplies the dura mater, communicating with a meningeal branch from the inferior maxillary nerve.

The **orbital or temporo-malar branch** arises in the sphenomaxillary fossa, enters the orbit by the sphenomaxillary fissure, and divides at the back of that cavity into two branches, temporal and malar.

The **temporal branch** runs in a groove along the outer wall of the orbit (in the malar bone), receives a branch of communication from the lachrymal, and, passing through a foramen in the malar bone, enters the temporal fossa. It ascends between the bone and substance of the Temporal muscle, pierces this muscle and the temporal fascia about an inch above the zygoma, and is distributed to the integument covering the temple and side of the forehead, communicating

¹ After it enters the infra-orbital canal, the nerve is frequently called the *infra-orbital*.

with the facial and auriculo-temporal branch of the inferior maxillary nerve. As it pierces the temporal fascia it gives off a slender twig, which runs between the two layers of the fascia to the outer angle of the orbit.

The *malar branch* passes along the external inferior angle of the orbit, emerges upon the face through a foramen in the malar bone, and, perforating the Orbicularis palpebrarum muscle, supplies the skin on the prominence of the cheek, and is named *subcutaneous malar*. It joins with the facial and the palpebral branches of the superior maxillary.

The *spheno-palatine branches*, two in number, descend to the spheno-palatine ganglion.

The *posterior superior dental branches* arise from the trunk of the nerve just as it is about to enter the infra-orbital canal; they are generally two in number,

FIG. 444.—Distribution of the second and third divisions of the fifth nerve and submaxillary ganglion.

but sometimes arise by a single trunk, and immediately divide and pass downward on the tuberosity of the superior maxillary bone. They give off several twigs to the gums and neighboring parts of the mucous membrane of the cheek (*superior gingival branches*). They then enter the posterior dental canals on the zygomatic surface of the superior maxillary bone, and, passing from behind forward in the substance of the bone, communicate with the middle dental nerve, and give off branches to the lining membrane of the antrum and three twigs to each of the molar teeth. These twigs enter the foramina at the apices of the fangs and supply the pulp.

The *middle superior dental branch* is given off from the superior maxillary nerve in the back part of the infra-orbital canal, and runs downward and forward in a special canal in the outer wall of the antrum to supply the two bicuspid teeth. It communicates with the posterior and anterior dental branches. At its point of

communication with the posterior branch is a slight thickening which has received the name of the *ganglion of Valentin*; and at its point of communication with the anterior branch is a second enlargement, which is called the *ganglion of Bochdalek*. Neither of these is probably a true ganglion.

The **anterior superior dental branch**, of large size, is given off from the superior maxillary nerve just before its exit from the infra-orbital foramen: it enters a special canal in the anterior wall of the antrum, and, coursing from before backward, divides into a series of branches which supply the incisor and canine teeth. It communicates with the middle dental branch, and gives off a *nasal branch*, which passes through a minute canal into the nasal fossa, and supplies the mucous membrane of the fore part of the inferior meatus and the floor of this cavity, communicating with the naso-palatine nerve from Meckel's ganglion.

FIG. 445.—The sphenopalatine ganglion and its branches.

The **palpebral branches** pass upward beneath the *Orbicularis palpebrarum*. They supply the integument and conjunctiva of the lower eyelid with sensation, joining at the outer angle of the orbit with the facial nerve and malar branch of the orbital.

The **nasal branches** pass inward; they supply the integument of the side of the nose and join with the nasal branch of the ophthalmic.

The **labial branches**, the largest and most numerous, descend beneath the *Levator labii superioris*, and are distributed to the integument of the upper lip, the mucous membrane of the mouth, and labial glands.

All these branches are joined, immediately beneath the orbit, by filaments from the facial nerve, forming an intricate plexus, the *infra-orbital*.

Sphenopalatine Ganglion (Fig. 445).

The **sphenopalatine ganglion** (*Meckel's*), the largest of the cranial ganglia, is deeply placed in the sphenopalatine fossa, close to the sphenopalatine foramen. It is triangular or heart-shaped, of a reddish-gray color, and is situated just below the superior maxillary nerve as it crosses the fossa.

Its Branches of Communication.—Like the other ganglia of the fifth nerve, it

possesses a motor, a sensory, and a sympathetic root. Its *sensory root* is derived from the superior maxillary nerve through its two sphenopalatine branches. These branches of the nerve, given off in the sphenomaxillary fossa, descend to the ganglion. Their fibres, for the most part, pass in front of the ganglion, as they proceed to their destination, in the palate and nasal fossa, and are not incorporated in the ganglionic mass; some few of the fibres, however, enter the ganglion, constituting its sensory root. Its *motor root* is derived from the facial nerve through the large superficial petrosal nerve, and its *sympathetic root* from the carotid plexus, through the large deep petrosal nerve. These two nerves join together to form a single nerve, the *Vidian*, before their entrance into the ganglion.

The *large superficial petrosal branch* (*nervus petrosus superficialis major*) is given off from the intumescencia ganglioformis in the aqueductus Fallopii; it passes through the hiatus Fallopii; enters the cranial cavity, and runs forward contained in a groove on the anterior surface of the petrous portion of the temporal bone, lying beneath the dura mater and the Gasserian ganglion. It then enters the cartilaginous substance which fills in the foramen lacerum medium basis cranii, and, joining with the large deep petrosal branch, forms the *Vidian nerve*.

The *large deep petrosal branch* (*nervus petrosus profundus*) is given off from the carotid plexus, and runs through the carotid canal on the outer side of the internal carotid artery. It then enters the cartilaginous substance which fills in the foramen lacerum medium, and joins with the large superficial petrosal nerve to form the *Vidian*.

The *Vidian nerve*, formed in the cartilaginous substance which fills in the middle lacerated foramen by the junction of the two preceding nerves, passes forward through the Vidian canal, with the artery of the same name, and, entering the sphenomaxillary fossa, joins the posterior angle of Meckel's ganglion.

Its *branches of distribution* are divisible into four groups: *ascending*, which pass to the orbit; *descending*, to the palate; *internal*, to the nose; and *posterior branches*, to the pharynx and nasal fossæ.

The *ascending branches* are two or three delicate filaments which enter the orbit by the sphenomaxillary fissure and supply the periosteum. Arnold describes and delineates these branches as ascending to the optic nerve. Bock describes a branch as going to the cavernous sinus to communicate with the sixth nerve, and Tiedemann, a communicating branch to the ophthalmic ganglion.

The *descending or palatine branches* are distributed to the roof of the mouth, the soft palate, tonsil, and lining membrane of the nose. They are almost a direct continuation of the sphenopalatine branches of the superior maxillary nerve, and are three in number—*anterior*, *middle*, and *posterior*.

The *anterior or large palatine nerve* descends through the posterior palatine canal, emerges upon the hard palate at the posterior palatine foramen, and passes forward through a groove in the hard palate nearly as far as the incisor teeth. It supplies the gums, the mucous membrane and glands of the hard palate, and communicates in front with the termination of the nasopalatine nerve. While in the posterior palatine canal it gives off *inferior nasal branches*, which enter the nose through openings in the palate bone, and ramify over the middle meatus and the middle and inferior spongy bones; and, at its exit from the canal a palatine branch is distributed to both surfaces of the soft palate.

The *middle or external palatine nerve* descends through one of the accessory palatine canals, distributing branches to the uvula, tonsil, and soft palate. It is occasionally wanting.

The *posterior or small palatine nerve* descends with a small artery through the small posterior palatine canal, emerging by a separate opening behind the posterior palatine foramen. It supplies the Levator palati and Azygos uvulæ muscles, the soft palate, tonsil, and uvula. The middle and posterior palatine join with the

tonsillar branches of the glosso-pharyngeal to form the plexus around the tonsil (*circulus tonsillaris*).

The *internal branches* are distributed to the septum and outer wall of the nasal fossæ. They are the superior nasal (anterior) and the naso-palatine.

The *superior nasal branches* (*anterior*), four or five in number, enter the back part of the nasal fossa by the spheno-palatine foramen. They supply the mucous membrane covering the superior and middle spongy bones, and that lining the posterior ethmoidal cells, a few being prolonged to the upper and back part of the septum. One branch is continued on to the inner surface of the anterior wall of the antrum, and there forms a communication with the anterior dental nerve. At the point of communication a swelling exists, denominated "the ganglion of Bochdalek," the nature of which seems to be, however, uncertain.

The *naso-palatine nerve* (*Cotunnii*) also enters the nasal fossa through the spheno-palatine foramen, and passes inward across the roof of the nose, below the orifice of the sphenoidal sinus, to reach the septum; it then runs obliquely downward and forward along the lower part of the septum, to the anterior palatine foramen, lying between the periosteum and mucous membrane. It descends to the roof of the mouth through the anterior palatine canal. The two nerves are here contained in separate and distinct canals, situated in the intermaxillary suture, and termed the foramina of Scarpa, the left nerve being usually anterior to the right one. In the mouth they become united, supply the mucous membrane behind the incisor teeth, and join with the anterior palatine nerve. The naso-palatine nerve occasionally furnishes a few small filaments to the mucous membrane of the septum.

The *posterior branches* are the pharyngeal (pterygo-palatine) and the upper posterior nasal branches.

The *pharyngeal nerve* (*pterygo-palatine*) is a small branch arising from the back part of the ganglion, being generally blended with the Vidian nerve. It passes through the pterygo-palatine canal with the pterygo-palatine artery, and is distributed to the mucous membrane of the upper part of the pharynx, behind the Eustachian tube.

The *upper posterior nasal branches* are a few twigs given off from the posterior part of the ganglion, which run backward in the sheath of the Vidian nerve to the mucous membrane at the back part of the roof, septum, and superior meatus of the nose and that covering the end of the Eustachian tube.

Inferior Maxillary Nerve (Fig. 444).

The **Inferior Maxillary Nerve** distributes branches to the teeth and gums of the lower jaw, the integument of the temple and external ear, the lower part of the face and lower lip, and the muscles of mastication; it also supplies the tongue with a large branch. It is the largest of the three divisions of the fifth, and is made up of two roots: a large or sensory root proceeding from the inferior angle of the Gasserian ganglion; and a small or motor root, which passes beneath the ganglion, and unites with the sensory root just after its exit through the foramen ovale. Immediately beneath the base of the skull this nerve divides into two trunks, anterior and posterior. Previous to its division the primary trunk gives off from its inner side a recurrent (meningeal) branch and the nerve to the Internal pterygoid muscle.

The **recurrent branch** is given off directly after its exit from the foramen ovale. It passes backward into the skull through the foramen spinosum with the middle meningeal artery. It divides into two branches, anterior and posterior, which accompany the main divisions of the artery and supply the dura mater. The anterior branch communicates with the meningeal branch of the superior maxillary nerve.

The **Internal Pterygoid Nerve**, given off from the inferior maxillary previous to its division, is intimately connected at its origin with the otic ganglion. It is a

long and slender branch, which passes inward to enter the deep surface of the Internal pterygoid muscle.

The *anterior* and smaller division, which receives nearly the whole of the motor root, divides into branches which supply the muscles of mastication. They are the masseteric, deep temporal, buccal, and external pterygoid.

The **masseteric branch** passes outward, above the External pterygoid muscle, in front of the temporo-maxillary articulation, and crosses the sigmoid notch with the masseteric artery to the Masseter muscle, in which it ramifies nearly as far as its anterior border. It occasionally gives a branch to the Temporal muscle and a filament to the articulation of the jaw.

The **deep temporal branches**, two in number, anterior and posterior, supply the deep surface of the Temporal muscle. The *posterior branch*, of small size, is placed at the back of the temporal fossa. It is sometimes joined with the masseteric branch. The *anterior branch* is reflected upward at the pterygoid ridge of the sphenoid to the front of the temporal fossa. Sometimes there are three deep temporal branches, the third branch (*middle deep temporal*) passing outward over the External pterygoid muscle to enter the deep surface of the Temporal muscle.

The **buccal branch** passes forward between the two heads of the External pterygoid, and downward beneath the inner surface of the coronoid process of the lower jaw, or through the fibres of the Temporal muscle, to reach the surface of the Buccinator, upon which it divides into a superior and an inferior branch. It gives a branch to the External pterygoid during its passage through that muscle, and a few ascending filaments to the Temporal muscle, one of which occasionally joins with the anterior branch of the deep temporal nerve. The *upper branch* supplies the integument and upper part of the Buccinator muscle, joining with the facial nerve round the facial vein. The *lower branch* passes forward to the angle of the mouth: it supplies the integument and Buccinator muscle, as well as the mucous membrane lining the inner surface of that muscle, and joins the facial nerve.¹

The **External Pterygoid Nerve** is most frequently derived from the buccal, but it may be given off separately from the anterior trunk of the nerve. It enters the muscle on its inner surface.

The *posterior* and larger division of the inferior maxillary nerve is for the most part sensory, but receives a few filaments from the motor root. It divides into three branches: auriculo-temporal, lingual (gustatory), and inferior dental.

The **Auriculo-temporal Nerve** generally arises by two roots, beneath which the middle meningeal artery passes. It runs backward beneath the External pterygoid muscle to the inner side of the neck of the lower jaw. It then turns upward with the temporal artery, between the external ear and condyle of the jaw, under cover of the parotid gland, and, escaping from beneath this structure, ascends over the zygoma and divides into two temporal branches.

The *branches of communication* are with the facial and with the otic ganglion. The branches of communication with the facial, usually two in number, pass forward from behind the neck of the condyle of the jaw, to join this nerve at the posterior border of the Masseter muscle. They form one of the principal branches of communication between the facial and the fifth nerve. The filaments of communication with the otic ganglion are derived from the commencement of the auriculo-temporal nerve.

The *branches of distribution* are—

Auricular, inferior and superior.	Articular.
Branches to the meatus auditorius.	Parotid.
Temporal, anterior and posterior.	

The *inferior auricular* arises behind the articulation of the jaw, and is distrib-

¹ There seems to be no reason to doubt that the branch supplying the Buccinator muscle is entirely a nerve of ordinary sensation, and that the true motor-supply of this muscle is from the facial.

uted to the ear below the external meatus: other filaments twine round the internal maxillary artery and communicate with the sympathetic. The *superior auricular* arises in front of the external ear, and supplies the integument covering the tragus and pinna.

Branches to the meatus auditorius, two in number, arise from the point of communication between the auriculo-temporal and facial nerves, and are distributed to the meatus.

A *branch to the temporo-maxillary articulation* is usually derived from the auriculo-temporal nerve.

The *parotid branches* supply the parotid gland.

The *anterior temporal* accompanies the temporal artery to the vertex of the skull, and supplies the integument of the temporal region, communicating with the facial nerve and the temporal branch of the temporo-malar from the superior maxillary. The *posterior temporal*, the smaller of the two, is distributed to the upper part of the pinna and the neighboring tissues.

The **Lingual Nerve** (*gustatory*) supplies the papillæ and mucous membrane of the tongue. It is deeply placed throughout the whole of its course. It lies at first beneath the External pterygoid muscle, together with the inferior dental nerve, being placed to the inner side of the latter nerve, and is occasionally joined to it by a branch which crosses the internal maxillary artery. The chorda tympani also joins it at an acute angle in this situation. The nerve then passes between the Internal pterygoid muscle and the inner side of the ramus of the jaw, and crosses obliquely to the side of the tongue over the Stylo-glossus muscle, and then between the Hyo-glossus muscle and deep part of the submaxillary gland: the nerve lastly runs across Wharton's duct, and along the side of the tongue to its apex, lying immediately beneath the mucous membrane.

The *branches of communication* are with the facial through the chorda tympani, the inferior dental and hypoglossal nerves, and the submaxillary ganglion. The branches to the submaxillary ganglion are two or three in number; those connected with the hypoglossal nerve form a plexus at the anterior margin of the Hyo-glossus muscle.

The *branches of distribution* are few in number. They supply the mucous membrane of the mouth, the gums, the sublingual gland, the filiform and fungiform papillæ and mucous membrane of the tongue; the terminal filaments communicate, at the tip of the tongue, with the hypoglossal nerve.

The **Inferior Dental** is the largest of the three branches of the inferior maxillary nerve. It passes downward with the inferior dental artery, at first beneath the External pterygoid muscle, and then between the internal lateral ligament and the ramus of the jaw to the dental foramen. It then passes forward in the dental canal of the inferior maxillary bone, lying beneath the teeth, as far as the mental foramen, where it divides into two terminal branches, incisor and mental.

The branches of the inferior dental are, the mylo-hyoid, dental, incisive, and mental.

The *mylo-hyoid* is derived from the inferior dental just as that nerve is about to enter the dental foramen. It descends in a groove on the inner surface of the ramus of the jaw, in which it is retained by a process of fibrous membrane. It reaches the under surface of the Mylo-hyoid muscle, and supplies it and the anterior belly of the Digastric, occasionally sending one or two filaments to the submaxillary gland.

The *dental branches* supply the molar and bicuspid teeth. They correspond in number to the fangs of those teeth: each nerve entering the orifice at the point of the fang and supplying the pulp of the tooth.

The *incisive branch* is continued onward within the bone to the middle line, and supplies the canine and incisor teeth.

The *mental branch* emerges from the bone at the mental foramen, and divides beneath the Depressor anguli oris into two or three branches; one descends to supply the skin of the chin, and another (sometimes two) ascends to supply the

skin and mucous membrane of the lower lip. These branches communicate freely with the facial nerve.

Two small ganglia are connected with the inferior maxillary nerve—the otic with the trunk of the nerve, and the submaxillary with its lingual branch.

Otic Ganglion (Fig. 446).

The **Otic Ganglion** (*Arnold's*) is a small, oval-shaped, flattened ganglion of a reddish-gray color, situated immediately below the foramen ovale, on the inner surface of the inferior maxillary nerve, and round the origin of the internal pterygoid nerve. It is in relation, *externally*, with the trunk of the inferior maxillary nerve, at the point where the motor root joins the sensory portion; *internally*, with the cartilaginous part of the Eustachian tube, and the origin of the Tensor palati muscle; *behind* it is the middle meningeal artery.

Branches of Communication.—This ganglion is connected with the internal pterygoid branch of the inferior maxillary nerve by two or three short, delicate filaments. From this it may obtain a motor root, and possibly also a sensory root, as these filaments from the nerve to the Internal pterygoid may contain sensory

FIG. 446.—The otic ganglion and its branches.

fibres. It communicates with the glosso-pharyngeal and facial nerves through the small superficial petrosal nerve continued from the tympanic plexus (page 779), and through this communication it probably receives its sensory root from the glosso-pharyngeal and its motor root from the facial; its communication with the sympathetic is effected by a filament from the plexus surrounding the middle meningeal artery. The ganglion also communicates with the auriculo-temporal nerve. This is probably a branch from the glosso-pharyngeal which passes to the ganglion, and through it and the auriculo-temporal nerve to the parotid gland.

Its *branches of distribution* are a filament to the Tensor tympani and one to the Tensor palati. The former passes backward on the outer side of the Eustachian tube; the latter arises from the ganglion, near the origin of the internal pterygoid nerve, and passes forward. The fibres of these nerves are, however, mainly derived from the nerve to the Internal pterygoid muscle. It also gives off a small communicating branch to the chorda tympani.

Submaxillary Ganglion (Fig. 444).

The **submaxillary ganglion** is of small size, fusiform in shape, and situated above the deep portion of the submaxillary gland, near the posterior border of the Mylo-hyoid muscle, being connected by filaments with the lower border of the lingual (gustatory) nerve.

Branches of Communication.—This ganglion is connected with the lingual (gustatory) nerve by a few filaments which join it separately at its fore and back part. It also receives a branch from the chorda tympani, by which it communicates with the facial, and communicates with the sympathetic by filaments from the sympathetic plexus around the facial artery.

Branches of Distribution.—These are five or six in number: they arise from the lower part of the ganglion, and supply the mucous membrane of the mouth and Wharton's duct, some being lost in the submaxillary gland. The branch of communication from the lingual to the fore part of the ganglion is by some regarded as a branch of distribution, by which filaments of the chorda tympani pass from the ganglion to the nerve, and by it are conveyed to the sublingual gland and the tongue.

Surface Marking.—It will be seen from the above description that the three terminal branches of the three divisions of the fifth nerve emerge from foramina in the bones of the skull and face on to the face: the terminal branch of the first division emerging through the supra-orbital foramen; that of the second through the infra-orbital foramen; and the third through the mental foramen. The supra-orbital foramen is situated at the junction of the internal and middle third of the supra-orbital arch between the internal and external angular processes. If a straight line is drawn from this point to the lower border of the inferior maxillary bone, so that it passes between the two bicuspid teeth in both jaws, it will pass over the infra-orbital and mental foramina, the former being situated about one centimetre (two-fifths of an inch) below the margin of the orbit, and the latter varying in position according to the age of the individual. In the adult it is midway between the upper and lower borders of the inferior maxillary bone; in the child it is nearer the lower border; and in the edentulous jaw of old age it is close to the upper margin.

Surgical Anatomy.—The fifth nerve may be affected in its entirety, or its sensory or motor root may be affected, or one of its primary main divisions. In injury to the sensory root there is anaesthesia of the whole of the side of the face on the side of the lesion, with the exception of the skin over the parotid gland; insensibility of the conjunctiva, followed by destructive inflammation of the cornea, partly from loss of trophic influence, and partly from the irritation produced by the presence of foreign bodies on it, which are not perceived by the patient, and therefore not expelled by the act of winking; dryness of the nose, loss to a considerable extent of the sense of taste, and diminished secretion of the lachrymal and salivary glands. In injury to the motor root there is impaired action of the lower jaw from paralysis of the muscles of mastication on the affected side.

The fifth nerve is often the seat of neuralgia, and each of the three divisions has been divided or a portion of the nerve excised for this affection. The supra-orbital nerve may be exposed by making an incision an inch and a half in length along the supra-orbital margin below the eyebrow, which is to be drawn upward, the centre of the incision corresponding to the supra-orbital notch. The skin and Orbicularis palpebrarum having been divided, the nerve can be easily found emerging from the notch and lying in some loose cellular tissue. It should be drawn up by a blunt hook and divided, or, what is better, a portion of it removed. The infra-orbital nerve has been divided at its exit by an incision on the cheek; or the floor of the orbit has been exposed, the infra-orbital canal opened up, and the anterior part of the nerve resected; or the whole nerve, together with Meckel's ganglion as far back as the foramen rotundum, has been removed. This latter operation, though undoubtedly a severe proceeding, appears to have been followed by the best results. The operation is performed as follows: The superior maxillary bone is first exposed by a T-shaped incision, one limb passing along the lower margin of the orbit, the other from the centre of this vertically down the cheek to the angle of the mouth. The nerve is then found, divided, and a piece of silk tied to it as a guide. A small trephine (one-half inch) is then applied to the bone below, but including, the infra-orbital foramen, and the antrum opened. The trephine is now applied to the posterior wall of the antrum, and the spheno-maxillary fossa exposed. The infra-orbital canal is now opened up from below by fine cutting-pliers or a chisel, and the nerve drawn down into the trephine hole, it being held on the stretch by means of the piece of silk: it is severed with fine curved scissors as near the foramen rotundum as possible, any branches coming off from the ganglion being also divided.¹ The inferior dental nerve has been divided at its exit from the foramen by an incision made through the mucous membrane where it is reflected from the alveolar process on to the lower lip; or a portion of the nerve has been resected by an incision on the cheek through the Masseter muscle,

¹ Carnochan, *Amer. Journ. Med. Science*, 1858, p. 136.

exposing the outer surface of the ramus of the jaw. A trephine was then applied over the position of the inferior dental foramen and the outer table removed, so as to expose the inferior dental canal. The nerve was dissected out of the portion of the canal exposed, and, having been divided after its exit from the mental foramen, it was by traction on the end exposed in the trephine hole, drawn out entire, and cut off as high up as possible.¹ The inferior dental nerve has also been divided by an incision within the mouth, the bony point guarding the inferior dental foramen forming the guide to the nerve. The buccal nerve may be divided by an incision through the mucous membrane of the mouth and the Buccinator just in front of the anterior border of the ramus of the lower jaw (Stimson).

The lingual (gustatory) nerve is occasionally divided with the view of relieving the pain in cancerous disease of the tongue. This may be done in that part of its course where it lies below and behind the last molar tooth. If a line is drawn from the middle of the crown of the last molar tooth to the angle of the jaw, it will cross the nerve, which lies about half an inch behind the tooth, parallel to the bulging alveolar ridge on the inner side of the body of the bone. If the knife is entered three-quarters of an inch behind and below the last molar tooth and carried down to the bone, the nerve will be divided. Hilton divided it opposite the second molar tooth, where it is covered only by the mucous membrane, and Lucas pulls the tongue forward and over to the opposite side, when the nerve can be seen standing out as a firm cord under the mucous membrane by the side of the tongue, and can be easily seized with a sharp hook and divided or a portion excised. This is a simple enough operation on the cadaver, but when the disease is extensive and has extended to the floor of the mouth, as is generally the case when division of the nerve is required, the operation is not practicable.

Sixth Nerve (Fig. 442).

The **Sixth or Abducent Nerve** supplies the External rectus muscle. Its *superficial origin* is by several filaments from the constricted part of the pyramid close to the pons, or from the lower border of the pons itself in the groove between this body and the medulla. Its *deep origin* is a little lower than the motor root of the fifth, and close to the median line, beneath the anterior portion of the fasciculus teres on the floor of the fourth ventricle.

The nerve pierces the dura mater on the basilar surface of the sphenoid bone, runs through a notch immediately below the posterior clinoid process, and enters the cavernous sinus. It passes forward through the sinus, lying on the outer side of the internal carotid artery. It enters the orbit through the sphenoidal fissure, and lies above the ophthalmic vein, from which it is separated by a lamina of dura mater. It then passes between the two heads of the External rectus, and is distributed to that muscle on its ocular surface.

Branches of Communication.—It is joined by several filaments from the carotid and cavernous plexus, by one from Meckel's ganglion (Bock), and another from the ophthalmic nerve.

The above-mentioned nerve, as well as the third, fourth, and the ophthalmic division of the fifth, as they pass to the orbit, bear a certain relation to each other in the cavernous sinus, at the sphenoidal fissure, and in the cavity of the orbit, which will now be described.

In the *cavernous sinus* (Fig. 384) the third, fourth, and ophthalmic division of the fifth are placed on the outer wall of the sinus, in their numerical order both from above downward and from within outward. The sixth nerve lies at the outer side of the internal carotid artery. As these nerves pass forward to the sphenoidal fissure, the third and fifth nerves become divided into branches, and the sixth approaches the rest, so that their relative position becomes considerably changed.

In the *sphenoidal fissure* (Fig. 447) the fourth and the frontal and lachrymal divisions of the ophthalmic lie upon the same plane, the former being most internal, the latter external, and they enter the cavity of the orbit above the muscles. The remaining nerves enter the orbit between the two heads of the External rectus. The superior division of the third is the highest of these; beneath this lies the nasal branch of the ophthalmic; then the inferior division of the third; and the sixth lowest of all.

In the *orbit* the fourth and the frontal and lachrymal divisions of the ophthalmic

¹ Mears, *Trans. Amer. Surg. Assoc.*, vol. ii. p. 469.

mic lie on the same plane immediately beneath the periosteum, the fourth nerve being internal and resting on the Superior oblique, the frontal resting on the Levator palpebræ, and the lachrymal on the External rectus. Next in order comes the superior division of the third nerve, lying immediately beneath the

FIG. 447.—Relations of structures passing through the sphenoidal fissure.

Superior rectus, and then the nasal branch of the ophthalmic, crossing the optic nerve from the outer to the inner side of the orbit. Beneath these is found the optic nerve, surrounded in front by the ciliary nerves, and having the lenticular ganglion on its outer side, between it and the External rectus. Below the optic is the inferior division of the third and the sixth, which lies on the outer side of the orbit.

Surgical Anatomy.—The sixth nerve is more frequently involved in fractures of the base of the skull than any other of the cranial nerves. The result of paralysis of this nerve is internal or convergent squint. When injured so that its function is destroyed, there is, in addition to the paralysis of the External rectus muscle, often a certain amount of contraction of the pupil, because some of the sympathetic fibres to the radiating muscle of the iris pass along with this nerve.

Seventh Nerve (Figs. 448, 449, 450).

The **Seventh or Facial Nerve** (*portio dura*) is the motor nerve of all the muscles of expression in the face and of the Platysma and Buccinator, the muscles of the External ear, the posterior belly of the Digastric, and the Stylo-hyoid. Through its chorda tympani it supplies the Lingualis; by its tympanic branch the Stapedius. Its *superficial origin* is from the lateral tract of the medulla oblongata, in the groove between the olivary and restiform bodies. Its *deep origin* is from a nucleus on the floor of the fourth ventricle, a little below and external to the nucleus of the sixth, above the level of the auditory strise.

FIG. 448.—The course and connections of the facial nerve in the temporal bone.

The auditory nerve (*portio mollis*) lies to its outer side, and between the two is a small fasciculus (*portio inter duram et mollem* of Wrisberg, or *pars intermedia*), which arises from the medulla and joins the facial nerve in the internal auditory meatus. At its origin it is frequently connected with both the nerves between which it lies.

The facial nerve, firmer, rounder, and smaller than the auditory, passes forward and outward upon the middle peduncle of the cerebellum, and enters the internal auditory meatus with the auditory nerve. Within the meatus the facial nerve lies first to the inner side of the auditory, and then in a groove upon that nerve. The *pars intermedia* is placed between the facial and auditory nerves in the internal auditory meatus; a few of its fibres frequently pass into the auditory nerve, while

the remainder join the facial. At the bottom of the meatus it is connected to this nerve by one or two slender filaments.

At the bottom of the meatus the facial nerve enters the aqueductus Fallopii, and follows the serpentine course of that canal through the petrous portion of the temporal bone, from its commencement at the internal meatus to its termination at the stylo-mastoid foramen. It is at first directed outward toward the inner wall of the tympanum, where it forms a reddish gangliform swelling (*intumescencia gangliiformis*, or *geniculate ganglion*), and is joined by several nerves; then bending suddenly backward, it runs in the internal wall of the tympanum, above the fenestra ovalis, and at the back of that cavity passes vertically downward behind the tympanum to the stylo-mastoid foramen. On emerging from this aperture it runs forward in the substance of the parotid gland, crosses the external carotid artery, and divides behind the ramus of the lower jaw into two primary branches, *temporo-facial* and *cervico-facial*, from which numerous offsets are distributed over the side of the head, face, and upper part of the neck, supplying the superficial muscles in these regions. As the primary branches and their offsets diverge from each other they present somewhat the appearance of a bird's claw; hence the name of *pes anserinus* is given to the divisions of the facial nerve in and near the parotid gland.

The communications of the facial nerve may be thus arranged:

In the internal auditory meatus	With the auditory nerve.
	With Meckel's ganglion by the large superficial petrosal nerve.
In the aqueductus Fallopii	With the otic ganglion by the small superficial petrosal nerve.
	With the sympathetic on the middle meningeal by the external superficial petrosal nerve.
At its exit from the stylo-mastoid foramen	With the glosso-pharyngeal.
	With the pneumogastric.
	With the carotid plexus.
	With the auricularis magnus.
	With the auriculo-temporal.
On the face	With the three divisions of the fifth.

In the internal auditory meatus some minute filaments pass between the facial and auditory nerves.

Opposite the hiatus Fallopii the gangliform enlargement on the facial nerve communicates with Meckel's ganglion by means of the large superficial petrosal nerve, which forms its motor root; with the otic ganglion, by the small superficial petrosal nerve; and with the sympathetic filaments accompanying the middle meningeal artery, by the external petrosal (Bidder). From the gangliform enlargement, according to Arnold, a twig is sent back to the auditory nerve.

At its exit from the stylo-mastoid foramen it sends a twig to the glosso-pharyngeal, another to the pneumogastric nerve, and communicates with the carotid plexus of the sympathetic, with the great auricular branch of the cervical plexus, with the auriculo-temporal branch of the inferior maxillary nerve in the parotid gland, and on the face with the terminal branches of the three divisions of the fifth.

BRANCHES OF DISTRIBUTION.

Within the aqueductus Fallopii	{ Tympanic.
	{ Chorda Tympani.
At its exit from the stylo-mastoid foramen	{ Posterior Auricular.
	{ Digastric.
	{ Stylo-hyoid.

On the face	{	Temporo-facial	{	Temporal.
				Malar.
				Infra-orbital.
	{	Cervico-facial	{	Buccal.

				Inframaxillary.

FIG. 449.—Plan of the facial nerve. (After Flower.)

The **tympanic branch** arises from the nerve opposite the pyramid; it passes through a small canal in the pyramid and supplies the Stapedius muscle.

The **chorda tympani** is given off from the facial as it passes vertically downward at the back of the tympanum, about a quarter of an inch before its exit from the stylo-mastoid foramen. It passes from below upward and forward in a distinct canal, and enters the cavity of the tympanum through an aperture (*iter chordæ posterius*) on its posterior wall between the opening of the mastoid cells and the attachment of the membrana tympani, and becomes invested with mucous membrane. It passes forward through the cavity of the tympanum, between the handle of the malleus and vertical ramus of the incus, to its anterior inferior angle, and emerges from that cavity through a foramen at the inner end of the Glaserian fissure, which is called the *iter chordæ anterioris*, or *canal of Huguier*. It then descends between the two Pterygoid muscles, meets the lingual nerve at an acute angle, and accompanies it to the submaxillary gland; part of it then joins the submaxillary ganglion; the rest is continued onward into the proper muscular fibres of the tongue—the Inferior lingualis muscle. A few of its fibres probably pass through the submaxillary ganglion to the sublingual gland. Before joining the lingual nerve it receives a small communicating branch from the otic ganglion.

The **Posterior auricular nerve** arises close to the stylo-mastoid foramen, and passes upward in front of the mastoid process, where it is joined by a filament from the auricular branch of the pneumogastric, and communicates with the

mastoid branch of the auricularis magnus and with the small occipital. As it ascends between the meatus and mastoid process it divides into two branches. The *auricular branch* supplies the Retrahens aurem and the small muscles on the cranial surface of the pinna. The *occipital branch*, the larger, passes backward along the superior curved line of the occipital bone, and supplies the occipital portion of the Occipito-frontalis.

The *digastric branch* usually arises by a common trunk with the Stylo-hyoid branch: it divides into several filaments, which supply the posterior belly of the

FIG. 450.—The nerves of the scalp, face, and side of the neck.

Digastric; one of these perforates that muscle to join the glosso-pharyngeal nerve.

The *stylo-hyoid* is a long slender branch, which passes inward, entering the Stylo-hyoid muscle about its middle; it communicates with the sympathetic filaments on the external carotid artery.

The *Temporo-facial*, the larger of the two terminal branches, passes upward and forward through the parotid glands, crosses the external carotid artery and temporo-maxillary vein, and passes over the neck of the condyle of the jaw, being connected in this situation with the auriculo-temporal branch of the inferior maxillary nerve, and divides into branches which are distributed over the temple and upper part of the face; these are divided into three sets—temporal, malar, and infra-orbital.

The *temporal branches* cross the zygoma to the temporal region, supplying the *Attrahens* and *Attollens aurem* muscles, and join with the temporal branch of the temporo-maxillary, a branch of the superior maxillary, and with the auriculo-temporal branch of the inferior maxillary. The more anterior branches supply the frontal portion of the *Occipito-frontalis*, the *Orbicularis palpebrarum*, and *Corrugator supercilii* muscles, joining with the supra-orbital and lachrymal branches of the ophthalmic.

The *malar branches* pass across the malar bone to the outer angle of the orbit, where they supply the *Orbicularis palpebrarum* muscle, joining with filaments from the lachrymal nerve; others supply the lower eyelid, joining with filaments of the malar branch (*subcutaneus malar*) of the superior maxillary nerve.

The *infra-orbital*, of larger size than the rest, pass horizontally forward to be distributed between the lower margin of the orbit and the mouth. The *superficial branches* run beneath the skin and above the superficial muscles of the face, which they supply: some branches are distributed to the *Pyramidalis nasi*, joining at the inner angle of the orbit with the infratrochlear and nasal branches of the ophthalmic. The *deep branches* pass beneath the *Zygomatici* and the *Levator labii superioris*, supplying them and the *Levator anguli oris*, and form a plexus (*infra-orbital*) by joining with the infra-orbital branch of the superior maxillary nerve and the buccal branches of the cervico-facial. This branch also supplies the *Levator labii superioris alæque nasi* and the small muscles of the nose.

The **Cervico-facial division of the facial nerve** passes obliquely downward and forward through the parotid gland, crossing the external carotid artery. In this situation it is joined by branches from the great auricular nerve. Opposite the angle of the lower jaw it divides into branches which are distributed on the lower half of the face and upper part of the neck. These may be divided into three sets—buccal, supramaxillary, and inframaxillary.

The *buccal branches* cross the *Masseter* muscle. They supply the *Buccinator* and *Orbicularis oris*, and join with the infra-orbital branches of the temporo-facial division of the nerve, and with filaments of the buccal branch of the inferior maxillary nerve.

The *supramaxillary branches* pass forward beneath the *Platysma* and *Depressor anguli oris*, supplying the muscles of the lower lip and chin, and communicating with the mental branch of the inferior dental nerve.

The *inframaxillary branches* run forward beneath the *Platysma*, and form a series of arches across the side of the neck over the suprahyoid region. One of these branches descends vertically to join with the *superficialis colli* nerve from the cervical plexus; others supply the *Platysma*.

Surgical Anatomy.—The facial nerve is more frequently paralyzed than any of the other of the cranial nerves. The paralysis may depend either upon (1) central causes—*i. e.* blood-clots or intracranial tumors pressing on the nerve before its entrance into the internal auditory meatus. It is also one of the nerves involved in "bulbar paralysis." Or (2) it may be paralyzed in its passage through the petrous bone by damage due to middle-ear disease or by fractures of the base. Or (3) it may be affected at or after its exit from the stylo-mastoid foramen. This is commonly known as "Bell's paralysis." It may be due to exposure to cold or to injury of the nerve, either from accidental wounds of the face or during some surgical operation, as removal of parotid tumors, opening of abscesses, or operations on the lower jaw.

When the cause is central the sixth nerve is usually also paralyzed, and there is hemiplegia on the opposite side. In these cases the electrical reactions are the same as in health; whereas when the paralysis is in the course of the nerve the reaction is usually lost. When the nerve is paralyzed in the petrous bone, in addition to the paralysis of the muscles of expression there is loss of taste in the anterior part of the tongue, and the patient is unable to recognize the difference between bitters and sweets, acids and salines, from involvement of the chorda tympani. The mouth is dry, because the salivary glands are not secreting, and the sense of hearing is affected from paralysis of the *Stapedius*. When the cause of the paralysis is from fracture of the base of the skull, the auditory nerve and the petrosal nerves, which are connected with the *intumescentia gangliiformis*, are also involved. When the injury is after the exit of the nerve from the stylo-mastoid foramen, all the muscles of expression, except the *Levator palpebræ*, together with the posterior belly of the *Digastric* and *Stylo-hyoid*, are paralyzed. There is smoothness of the forehead and the patient is unable to frown: the eyelids cannot be closed and the lower lid droops, so that the punctum is no longer in contact with the globe, and the

tears run down the cheek; there is smoothness of the cheek and loss of the naso-labial furrow; the nostril cannot be dilated; the mouth is drawn to the sound side, and there is inability to whistle; food collects between the cheek and gum from paralysis of the Buccinator. The facial nerve is at fault in cases of so-called "histrionic spasm," which consists in an almost constant and uncontrollable twitching of the muscles of the face. This twitching is sometimes so severe as to cause great discomfort and annoyance to the patient and to interfere with sleep, and for its relief the facial nerve has been stretched. The operation is performed by making an incision behind the ear from the root of the mastoid process to the angle of the jaw. The parotid is turned forward, and the dissection carried along the anterior border of the Sterno-mastoid muscle and mastoid process until the upper border of the posterior belly of the Digastric is found. The nerve is parallel to this on about a level of the middle of the mastoid process. When found, the nerve must be stretched by passing a blunt hook beneath it and pulling it forward and outward. Too great force must not be used, for fear of permanent injury to the nerve.

Eighth Nerve.

The **Eighth or Auditory Nerve** (*portio mollis*) is the special nerve of the sense of hearing, being distributed exclusively to the internal ear.

Its *superficial origin* is from the groove between the olivary and restiform bodies at the lower border of the pons. It lies external to the facial nerve. It has two *deep origins*: 1. From a prominence, the *auditory tubercle*, on the outer side of the inferior fovea on the floor of the fourth ventricle. 2. From a nucleus situated at the lateral angle of the same ventricle. The auditory nerve winds round the restiform body, and passes forward across the posterior border of the middle peduncle of the cerebellum, in company with the facial nerve, from which it is partially separated by a small artery (auditory). It then enters the internal auditory meatus with the facial nerve. At the bottom of the meatus it receives one or two filaments from the facial nerve, and then divides into two branches, *cochlear* and *vestibular*, which are distributed, the former to the cochlea, the latter to the vestibule and semicircular canals. The auditory nerve is soft in texture (hence the name *portio mollis*), and is destitute of neurilemma. The distribution of the auditory nerve in the internal ear will be found described along with the anatomy of that organ in a subsequent page.

Surgical Anatomy.—The auditory nerve is frequently injured, together with the facial nerve, in fractures of the middle fossa of the base of the skull implicating the internal auditory meatus. The nerve may be either torn across, producing permanent deafness, or it may be bruised or pressed upon by extravasated blood or inflammatory exudation, when the deafness will in all probability be temporary. The nerve may also be injured by violent blows on the head without fracture, and deafness may arise from loud explosions from dynamite, etc., probably from some lesion of this nerve, which is more liable to be injured than the other cranial nerves on account of its structure. The test that the nerve is destroyed and that the deafness is not due to some lesion of the auditory apparatus is obtained by placing a vibrating tuning-fork on the head. The vibrations will be heard in cases where the auditory apparatus is at fault, but not in cases of destruction of the auditory nerve.

Ninth Pair (Figs. 451, 452, 453).

The **Ninth or Glosso-pharyngeal Nerve** (Figs. 451, 452, 453) is distributed, as its name implies, to the tongue and pharynx, being the nerve of sensation to the mucous membrane of the pharynx, fauces, and tonsil, and a special nerve of taste to all the parts of the tongue to which it is distributed. Its *superficial origin* is by three or four filaments closely connected together, from the upper part of the medulla oblongata, in the groove between the olivary and the restiform body.

Its *deep origin* may be traced through the fasciculi of the lateral tract to a nucleus of gray matter at the lower part of the floor of the fourth ventricle, beneath the inferior fovea, below the inner nucleus of the auditory nerve, and above that of the pneumogastric. From its superficial origin it passes outward across the flocculus, and leaves the skull at the central part of the jugular foramen, in a separate sheath of the dura mater, in front of the pneumogastric and spinal accessory nerves (Fig. 386). In its passage through the jugular foramen it grooves the lower border of the petrous portion of the temporal bone, and

at its exit from the skull passes forward between the jugular vein and internal carotid artery, and descends in front of the latter vessel, and beneath the styloid process and the muscles connected with it, to the lower border of the Stylo-pharyngeus. The nerve now curves inward, forming an arch on the side of the neck, and lying upon the Stylo-pharyngeus and Middle constrictor of the pharynx, above the superior laryngeal nerve. It then passes beneath the Hyoglossus, and is finally distributed to the mucous membrane of the fauces and base of the tongue, and the mucous glands of the mouth and tonsil.

In passing through the jugular foramen the nerve presents, in succession, two gangliform enlargements. The superior, the smaller, is called the *jugular ganglion*; the inferior and larger, the *petrous ganglion*, or the *ganglion of Andersch*.

The **superior, or jugular, ganglion** is situated in the upper part of the groove in which the nerve is lodged during its passage through the jugular foramen. It is of very small size, and involves only the lower part of the trunk of the nerve. It is usually regarded as a segmentation from the lower ganglion.

The **inferior, or petrous, ganglion** is situated in a depression in the lower border of the petrous portion of the temporal bone; it is larger than the former and involves the whole of the fibres of the nerve. From this ganglion arise those filaments which connect the glosso-pharyngeal with the pneumogastric and sympathetic nerves.

The *branches of communication* are with the pneumogastric, sympathetic, and facial.

The branches to the pneumogastric are two filaments, arising from the petrous ganglion, one to its auricular branch, and one to the upper ganglion of the pneumogastric.

The branch to the sympathetic, also arising from the petrous ganglion, is connected with the superior cervical ganglion.

The branch of communication with the facial perforates the posterior belly of the Digastric. It arises from the trunk of the nerve below the petrous ganglion, and joins the facial just after its exit from the stylo-mastoid foramen.

The *branches of distribution* are the tympanic, carotid, pharyngeal, muscular, tonsillar, and lingual.

The **tympanic branch** (*Jacobson's nerve*) arises from the petrous ganglion, and enters a small bony canal in the lower surface of the petrous portion of the temporal bone, the lower opening of which is situated on the bony ridge which separates the carotid canal from the jugular fossa. It ascends to the tympanum, enters that cavity by an aperture in its floor close to the inner wall, and divides into branches which are contained in grooves upon the surface of the promontory, forming the tympanic plexus.

Its *branches of distribution* are—one to the fenestra rotunda, one to the fenestra ovalis, and one to the lining membrane of the tympanum and Eustachian tube.

Its *branches of communication* are three, and occupy separate grooves on the surface of the promontory. One branch, the *small deep petrosal*, arches forward and downward to the carotid canal to join the carotid plexus. A second, the *long petrosal nerve*, runs forward through a canal close to or in the processus cochleariformis and enters the foramen lacerum medium, where it joins the carotid plexus of the sympathetic, and generally the large superficial petrosal nerve. The third branch runs upward through the substance of the petrous portion of the temporal bone. In its course it passes by the gangliform enlargement of the facial nerve, and, receiving a connecting filament from it, becomes the *small superficial petrosal nerve*. This nerve enters the skull through a small aperture situated external to the hiatus Fallopii on the anterior surface of the

FIG. 451.—Nerves of the eighth pair, their origin, ganglia, and communications.

FIG. 452.—Plan of the glossopharyngeal, pneumogastric, and spinal accessory nerves. (After Flower.)

petrous bone, courses forward across the base of the skull, and emerges through a foramen in the middle fossa (sometimes in the foramen ovale), and joins the otic ganglion.

The **carotid branches** descend along the trunk of the internal carotid artery as far as its commencement, communicating with the pharyngeal branch of the pneumogastric and with branches of the sympathetic.

The **pharyngeal branches** are three or four filaments which unite opposite the Middle constrictor of the pharynx with the pharyngeal branches of the pneumogastric, the external laryngeal, and sympathetic nerves to form the pharyngeal plexus, branches from which perforate the muscular coat of the pharynx to supply the muscles and mucous membrane.

The **muscular branch** is distributed to the Stylo-pharyngeus.

The **tonsillar branches** supply the tonsil, forming a plexus (*circulus tonsillaris*) around this body, from which branches are distributed to the soft palate and fauces, where they communicate with the palatine nerves.

The **lingual branches** are two in number: one supplies the circumvallate papillæ and the mucous membrane covering the surface of the base of the tongue; the other perforates its substance, and supplies the mucous membrane and follicular glands of the tongue and anterior surface of the epiglottis.

Tenth Pair (Figs. 452, 453).

The **Tenth or Pneumogastric Nerve** (*nervus vagus* or *par vagum*) has a more extensive distribution than any of the other cranial nerves, passing through the neck and thorax to the upper part of the abdomen. It is composed of both motor and sensory fibres. It supplies the organs of voice and respiration with motor and sensory fibres, and the pharynx, œsophagus, stomach, and heart with motor fibres. Its *superficial origin* is by eight or ten filaments from the groove between the olivary and the restiform body below the glosso-pharyngeal; its *deep origin* may be traced through the fasciculi of the medulla, to terminate in a nucleus of gray matter at the lower part of the floor of the fourth ventricle, below and continuous with the nucleus of origin of the

FIG. 453.—Course and distribution of the eighth pair of nerves.

glosso-pharyngeal. The filaments become united and form a flat cord, which passes outward beneath the flocculus to the jugular foramen, through which it emerges from the cranium. In passing through this opening the pneumogastric accompanies the spinal accessory, being contained in the same sheath of dura mater with it, a membranous septum separating it from the glosso-pharyngeal, which lies in front (Fig. 386). The nerve in this situation presents a well-marked ganglionic enlargement, which is called the *jugular ganglion*, or the *ganglion of the root of the pneumogastric*: to it the accessory part of the spinal accessory nerve is connected by one or two filaments. After the exit of the nerve from the jugular foramen the nerve is joined by the accessory portion of the spinal accessory, and enlarged into a second gangliform swelling, called the *ganglion inferius*, or the *ganglion of the trunk of the nerve*, through which the fibres of the spinal accessory pass unchanged, being principally distributed to the pharyngeal and superior laryngeal branches of the vagus; but some of the filaments from it are continued into the trunk of the vagus below the ganglion, to be distributed with the recurrent laryngeal nerve, and probably also with the cardiac nerves. The nerve passes vertically down the neck within the sheath of the carotid vessels lying between the internal carotid artery and internal jugular vein as far as the thyroid cartilage, and then between the same vein and the common carotid to the root of the neck. Here the course of the nerve becomes different on the two sides of the body.

On the *right side* the nerve passes across the subclavian artery between it and the right innominate vein, and descends by the side of the trachea to the back part of the root of the lung, where it spreads out in a plexiform network (*posterior pulmonary*), from the lower part of which two cords descend upon the œsophagus, on which they divide, forming, with branches from the opposite nerve, the œsophageal plexus (*plexus gulæ*); below, these branches are collected into a single cord, which runs along the back part of the œsophagus, enters the abdomen, and is distributed to the posterior surface of the stomach, joining the left side of the solar plexus, and sending filaments to the splenic plexus and a considerable branch to the cœliac plexus.

On the *left side* the pneumogastric nerve enters the chest between the left carotid and subclavian arteries, behind the left innominate vein. It crosses the arch of the aorta and descends behind the root of the left lung, forming the *posterior pulmonary plexus*, and along the anterior surface of the œsophagus, where it unites with the nerve of the right side in forming the *plexus gulæ*, to the stomach, distributing branches over its anterior surface, some extending over the *great cul-de-sac*, and others along the lesser curvature. Filaments from these branches enter the gastro-hepatic omentum and join the hepatic plexus.

The *ganglion of the root* is of a grayish color, circular in form, about two lines in diameter, and resembles the ganglion on the large root of the fifth nerve.

Connecting Branches.—To this ganglion the accessory portion of the spinal accessory nerve is connected by several delicate filaments; it also has a communicating twig with the petrous ganglion of the glosso-pharyngeal, with the facial nerve by means of its auricular branch, and with the sympathetic by means of an ascending filament from the superior cervical ganglion.

The *ganglion of the trunk* (inferior) is a plexiform cord, cylindrical in form, of a reddish color, and about an inch in length; it involves the whole of the fibres of the nerve, and passing through it is the accessory portion of the spinal accessory nerve, which blends with the pneumogastric below the ganglion, and is then principally continued into its pharyngeal and superior laryngeal branches.

Connecting Branches.—This ganglion is connected with the hypoglossal, the superior cervical ganglion of the sympathetic, and the loop between the first and second cervical nerves.

The branches of the pneumogastric are—

In the jugular fossa	{ Meningeal.
	{ Auricular.
	{ Pharyngeal.
In the neck	{ Superior laryngeal.
	{ Recurrent laryngeal.
	{ Cervical cardiac.
	{ Thoracic cardiac.
In the thorax	{ Anterior pulmonary.
	{ Posterior pulmonary.
	{ Esophageal.
In the abdomen	{ Gastric.

The **meningeal branch** is a recurrent branch given off from the ganglion of the root in the jugular foramen. It passes backward, and is distributed to the dura mater covering the posterior fossa of the base of the skull.

The **auricular branch** (*Arnold's*) arises from the ganglion of the root, and is joined soon after its origin by a filament from the petrous ganglion of the glosso-pharyngeal; it passes outward behind the jugular vein, and enters a small canal on the outer wall of the jugular fossa. Traversing the substance of the temporal bone, it crosses the aqueductus Fallopii about two lines above its termination at the stylo-mastoid foramen; here it gives off an ascending branch, which joins the facial: the continuation of the nerve reaches the surface by passing through the auricular fissure between the mastoid process and the external auditory meatus, and divides into two branches, one of which communicates with the posterior auricular nerve, while the other supplies the integument at the back part of the pinna and the posterior part of the external auditory meatus.

The **pharyngeal branch**, the principal motor nerve of the pharynx, arises from the upper part of the inferior ganglion of the pneumogastric. It consists principally of filaments from the accessory portion of the spinal accessory: it passes across the internal carotid artery (in front or behind) to the upper border of the Middle constrictor, where it divides into numerous filaments, which join with those from the glosso-pharyngeal, superior laryngeal (its external branch), and sympathetic, to form the pharyngeal plexus, from which branches are distributed to the muscles and mucous membrane of the pharynx and the muscles of the soft palate. From the pharyngeal plexus a minute filament is given off, which descends and joins the hypoglossal nerve as it winds round the occipital artery.

The **superior laryngeal** is the nerve of sensation to the larynx. It is larger than the preceding, and arises from the middle of the inferior ganglion of the pneumogastric. It consists principally of filaments from the accessory portion of the spinal accessory. In its course it receives a branch from the superior cervical ganglion of the sympathetic. It descends by the side of the pharynx behind the internal carotid, where it divides into two branches, the external and internal laryngeal.

The **external laryngeal branch**, the smaller, descends by the side of the larynx, beneath the Sterno-thyroid, to supply the Crico-thyroid muscle. It gives branches to the pharyngeal plexus and the Inferior constrictor, and communicates with the superior cardiac nerve, behind the common carotid.

The **internal laryngeal branch** descends to the opening in the thyro-hyoid membrane, through which it passes with the superior laryngeal artery, and is distributed to the mucous membrane of the larynx. A small branch communicates with the recurrent laryngeal nerve. The branches to the mucous membrane are distributed, some in front to the epiglottis, the base of the tongue, and the epiglottidean glands; while others pass backward, in the aryteno-epiglottidean fold, to supply the mucous membrane surrounding the superior orifice of the larynx, as well as the membrane which lines the cavity of the larynx as low down as the vocal cord. The filament which joins with the recurrent laryngeal descends beneath the mucous membrane on the inner surface of the thyroid cartilage, where the two nerves become united.

The **inferior or recurrent laryngeal**, so called from its reflected course, is the motor nerve of the larynx. It arises on the right side, in front of the subclavian artery; winds from before backward round that vessel, and ascends obliquely to the side of the trachea, behind the common carotid and inferior thyroid arteries. On the left side it arises in front of the arch of the aorta, and winds from before backward round the aorta at the point where the remains of the ductus arteriosus are connected with it, and then ascends to the side of the trachea. The nerves on both sides ascend in the groove between the trachea and œsophagus, and, passing under the lower border of the Inferior constrictor muscle, enter the larynx behind the articulation of the inferior cornu of the thyroid cartilage with the cricoid, being distributed to all the muscles of the larynx, except the Crico-thyroid. It communicates with the Superior laryngeal nerve.

The recurrent laryngeal, as it winds round the subclavian artery and aorta, gives off several cardiac filaments, which unite with the cardiac branches from the pneumogastric and sympathetic. As it ascends in the neck it gives off œsophageal branches, more numerous on the left than on the right side, which supply the mucous membrane and muscular coat of the œsophagus; tracheal branches to the mucous membrane and muscular fibres of the trachea: and some pharyngeal filaments to the Inferior constrictor of the pharynx.

The **cervical cardiac branches**, two or three in number, arise from the pneumogastric, at the upper and lower part of the neck.

The *superior branches* are small, and communicate with the cardiac branches of the sympathetic. They can be traced to the great or deep cardiac plexus.

The *inferior branches*, one on each side, arise at the lower part of the neck, just above the first rib. On the right side this branch passes in front or by the side of the arteria innominata, and communicates with one of the cardiac nerves proceeding to the great or deep cardiac plexus. On the left side it passes in front of the arch of the aorta and joins the superficial cardiac plexus.

The **thoracic cardiac branches**, on the right side, arise from the trunk of the pneumogastric as it lies by the side of the trachea, and from its recurrent laryngeal branch, but on the left side from the recurrent nerve only; passing inward, they terminate in the deep cardiac plexus.

The **anterior pulmonary branches**, two or three in number, and of small size, are distributed on the anterior aspect of the root of the lungs. They join with filaments from the sympathetic, and form the *anterior pulmonary plexus*.

The **posterior pulmonary branches**, more numerous and larger than the anterior, are distributed on the posterior aspect of the root of the lung: they are joined by filaments from the third and fourth (sometimes also first and second) thoracic ganglia of the sympathetic, and form the *posterior pulmonary plexus*. Branches from both plexuses accompany the ramification of the air-tubes through the substance of the lungs.

The **œsophageal branches** are given off from the pneumogastric both above and below the pulmonary branches. The lower are more numerous and larger than the upper. They form, together with branches from the opposite nerve, the *œsophageal plexus* or *plexus gular*.

The **gastric branches** are the terminal filaments of the pneumogastric nerve. The nerve on the right side is distributed to the posterior surface of the stomach, and joins the left side of the celiac plexus and the splenic plexus. The nerve on the left side is distributed over the anterior surface of the stomach, some filaments passing across the great *cul-de-sac*, and others along the lesser curvature. They unite with branches of the right nerve and with the sympathetic, some filaments passing through the lesser omentum to the hepatic plexus.

Surgical Anatomy.—The laryngeal nerves are of considerable importance in considering some of the morbid conditions of the larynx. When the peripheral terminations of the superior laryngeal nerve are irritated by some foreign body passing over them, reflex spasm of the glottis is the result. When the trunk of this same nerve is pressed upon by, for instance, a goitre or an aneurism of the upper part of the carotid, we have a peculiar dry, brassy cough. When the

nerve is paralyzed, we have anaesthesia of the mucous membrane of the larynx, so that foreign bodies can readily enter the cavity, and, in consequence of its supplying the crico-thyroid muscle, the vocal cords cannot be made tense, and the voice is deep and hoarse. Paralysis of the superior laryngeal nerves may be the result of bulbar paralysis, may be a sequel to diphtheria, when both nerves are usually involved, or it may, though less commonly, be caused by the pressure of tumors or aneurisms, when the paralysis is generally unilateral. Irritation of the inferior laryngeal nerves produces spasm of the muscles of the larynx. When both these recurrent nerves are paralyzed, the vocal cords are motionless, in the so-called "cadaveric position"—that is to say, in the position in which they are found in ordinary tranquil respiration—neither closed as in phonation, nor open as in deep inspiratory efforts. When one recurrent nerve is paralyzed, the cord of the same side is motionless, while the opposite one crosses the middle line to accommodate itself to the affected one; hence phonation is present, but the voice is altered and weak in timbre. The recurrent laryngeal nerves may be paralyzed in bulbar paralysis or after diphtheria, when it usually affects both sides; or they may be affected by the pressure of aneurisms of the aorta, innominate or subclavian arteries; by mediastinal tumors; by bronchocele; or by cancer of the upper part of the oesophagus, when the paralysis is often unilateral.

Eleventh Pair (Figs. 452, 453).

The **Eleventh or Spinal Accessory Nerve** consists of two parts—one the accessory part to the vagus, and the other the spinal portion.

The **accessory part** is the smaller of the two. Its *superficial origin* is by four or five delicate filaments from the side of the medulla, below the roots of the vagus. Its *deep origin* may be traced to a nucleus of gray matter at the back of the medulla, extending from the level of the top of the calamus scriptorius as far down as the intermedio-lateral tract of the spinal cord. It passes outward to the jugular foramen, where it joins with the spinal portion and with the upper ganglion of the vagus by one or two filaments, and is then continued over the surface of this ganglion to join the trunk of the vagus after its exit from the jugular foramen. The fibres of the accessory part then pass unchanged through the inferior ganglion, or ganglion of the trunk of the vagus, to be distributed principally to the pharyngeal and superior laryngeal branches of the pneumogastric. Through the pharyngeal branch it probably supplies the muscles of the soft palate (see page 425). Some few filaments from it are continued into the trunk of the vagus below the ganglion, to be distributed with the recurrent laryngeal nerve and probably also with the cardiac nerves.

The **spinal portion** is firm in texture. Its *superficial origin* is by several filaments from the lateral tract of the cord, as low down as the sixth cervical nerve. Its *deep origin* may be traced to the intermedio-lateral tract of the gray matter of the cord. This portion of the nerve ascends between the ligamentum denticulatum and the posterior roots of the spinal nerves, enters the skull through the foramen magnum, and is then directed outward to the jugular foramen, through which it passes, lying in the same sheath as the pneumogastric, but separated from it by a fold of the arachnoid. In the jugular foramen it receives one or two filaments from the accessory portion. At its exit from the jugular foramen it passes backward, either in front of or behind the internal jugular vein, and descends obliquely behind the Digastric and Stylo-hyoid muscles to the upper part of the Sterno-mastoid. It pierces that muscle, and passes obliquely across the occipital triangle, to terminate in the deep surface of the Trapezius. This nerve gives several branches to the Sterno-mastoid during its passage through it, and joins in its substance with branches from the second cervical, which supply the muscle. In the occipital triangle it joins with the second and third cervical nerves and assists in the formation of the cervical plexus. Beneath the Trapezius it joins with the third and fourth cervical nerves to form a sort of plexus, from which fibres are distributed to the muscle.

Surgical Anatomy.—In cases of spasmodic torticollis in which all previous palliative treatment has failed, and the spasms are so severe as to undermine the patient's health, division or excision of a portion of the spinal accessory nerve has been resorted to. This may be done either along the anterior or posterior border of the Sterno-mastoid muscle. The former operation is performed by making an incision from the apex of the mastoid process, three inches in length, along the anterior border of the Sterno-mastoid muscle. The anterior border of the muscle is

defined and pulled backward, so as to stretch the nerve, which is then to be sought for beneath the Digastric muscle, about two inches below the apex of the mastoid process. The other operation consists in making an incision along the posterior border of the muscle, so that the centre of the incision corresponds to the middle of this border of the muscle. The superficial structures having been divided and the border of the muscle defined, the nerve is to be sought for as it emerges from the muscle to cross the occipital triangle. When found, it is to be traced upward through the muscle, and a portion of it excised above the point where it gives off its branches to the Sterno-mastoid. In this operation one of the descending branches of the superficial cervical plexus is liable to be mistaken for the nerve.

Twelfth Pair (Figs. 453, 454).

The **Twelfth** or **Hypoglossal Nerve** is the motor nerve of the tongue. Its *superficial origin* is by several filaments, from ten to fifteen in number, from the

FIG. 454.—Plan of the hypoglossal nerve. (After Flower.)

groove between the pyramidal and olivary bodies, in a continuous line with the anterior roots of the spinal nerves. Its *deep origin* can be traced to a nucleus of gray matter on the floor of the fourth ventricle, on either side of the median line, extending from the level of the auditory striæ to the lowest point of the ventricle of Arantius. The filaments of this nerve are collected into two bundles which perforate the dura mater separately, opposite the anterior condyloid foramen, and unite together after their passage through it. In those cases in which the anterior condyloid foramen in the occipital bone is double these two portions of the nerve are separated by the small piece of bone which divides the foramen. The nerve descends almost vertically to a point corresponding with the angle of the jaw. It is at first deeply seated beneath the internal carotid artery and internal jugular vein, and intimately connected with the pneumogastric nerve; it then passes forward between the vein and artery, and lower down in the neck becomes superficial below the Digastric muscle. The nerve then loops round the occipital artery, and crosses the external carotid below the tendon of the Digastric muscle. It

passes beneath the Mylo-hyoid muscle, lying between it and the Hyo-glossus, and communicates at the anterior border of the latter muscle with the lingual (gustatory) nerve; it is then continued forward in the fibres of the Genio-hyo-glossus muscle as far as the tip of the tongue, distributing branches to its substance.

The *branches of communication* are—with the

Pneumogastric.
Sympathetic.

First and Second Cervical Nerves.
Lingual (gustatory).

The communication with the pneumogastric takes place close to the exit of the nerve from the skull, numerous filaments passing between the hypoglossal and

FIG. 455.—Hypoglossal nerve, cervical plexus, and their branches.

lower ganglion of the pneumogastric; sometimes the two nerves are united so as to form one mass. It also communicates with the pharyngeal plexus by a minute filament as it winds round the occipital artery.

The communication with the sympathetic takes place opposite the atlas by branches derived from the superior cervical ganglion, and in the same situation the nerve is joined by a filament derived from the loop connecting the first two cervical nerves.

The communication with the lingual (gustatory) takes place near the anterior border of the Hyo-glossus muscle by numerous filaments which ascend upon it.

The *branches of distribution* are—the

Meningeal.
Descendens hypoglossi.

Thyro-hyoid.
Muscular.

Meningeal Branches.—As the hypoglossal nerve passes through the anterior

condyloid foramen it gives off, according to Luschka, several filaments to the dura mater in the posterior fossa of the base of the skull.

The **descendens hypoglossi** is a long slender branch which quits the hypoglossal where it turns round the occipital artery. It descends obliquely across the sheath of the carotid vessels, and joins the communicating branches from the second and third cervical nerves, just below the middle of the neck, to form a loop. From the convexity of this loop branches pass forward to supply the Sterno-hyoid, Sterno-thyroid, and both bellies of the Omo-hyoid. According to Arnold, another filament descends in front of the vessels into the chest and joins the cardiac and phrenic nerves. The descendens hypoglossi is occasionally contained in the sheath of the carotid vessels, being sometimes placed over, and sometimes beneath, the internal jugular vein.

The **thyro-hyoid** is a small branch arising from the hypoglossal near the posterior border of the Hyo-glossus; it passes obliquely across the great cornu of the hyoid bone and supplies the Thyro-hyoid muscle.

The **muscular branches** are distributed to the Stylo-glossus, Hyo-glossus, Genio-hyoid, and Genio-hyo-glossus muscles. At the under surface of the tongue numerous slender branches pass upward into the substance of the organ to supply its muscular structure.

Surgical Anatomy.—The hypoglossal nerve is an important guide in the operation of ligature of the lingual artery (see page 555). It runs forward just above the great cornu of the hyoid bone, and forms the upper boundary of the triangular space in which the artery is to be sought for.

THE SPINAL NERVES.

The **spinal nerves** are so called because they take their origin from the spinal cord, and are transmitted through the intervertebral foramina on either side of the spinal column. There are thirty-one pairs of spinal nerves, which are arranged into the following groups, corresponding to the region of the spine through which they pass :

Cervical	8 pairs.
Dorsal	12 "
Lumbar	5 "
Sacral	5 "
Coccygeal	1 pair.

It will be observed that each group of nerves corresponds in number with the vertebræ in that region, except the cervical and coccygeal.

Each spinal nerve arises by two roots, an anterior or motor root, and a posterior or sensory root.

Roots of the Spinal Nerves.

The Anterior Roots.—The *superficial origin* is from a somewhat irregular series of depressions which map out a longitudinal area on the antero-lateral column of the spinal cord, gradually approaching toward the anterior median fissure as they descend.

The *deep origin* can be traced to the anterior part of the antero-lateral column; the roots, after penetrating horizontally through the longitudinal fibres of this tract, enter the gray substance, where their fibrils diverge in several directions: some, passing *inward*, are continued across the anterior commissure in front of the central canal, to become continuous with the axis-cylinder processes of the large cells of the anterior cornua of the opposite side; others terminate in the mesial group of cells of the anterior column of the same side; other fibrils pass *outward*, some to become continuous with the axis-cylinder processes of the group of cells in the lateral part of the anterior column; and others enter the lateral column of the same side, where, turning upward, they pursue their course as longitudinal fibres. The remaining fibrils pass *backward* to the posterior horn, where they are continuous with the axis-cylinders of the cells at the base of the posterior cornu.

The Posterior Roots.—The *superficial origin* is from the postero-lateral fissure of the cord. The *deep origin* is from the gray substance of the posterior cornu, either directly through the substantia gelatinosa, or indirectly, by first passing through the white matter of the posterior column and winding round in front of the caput cornu. Those which enter the gray matter at once for the most part turn upward and downward, and become continuous with the fine nerve-plexus in the central portion of the gray matter; some few fibres pass transversely through the posterior commissure to the opposite side, and others into the anterior cornu of the same side. Those fibres which enter the gray matter in front of the caput cornu reach the posterior vesicular column (Clark's column) and blend with it, a few fibres passing through it, to become longitudinal in the posterior column of the cord.

The *anterior roots* are smaller than the posterior, devoid of ganglionic enlargement, and their component fibrils are collected into two bundles near the intervertebral foramina.

The *posterior roots* of the nerves are larger, but the individual filaments are finer and more delicate than those of the anterior. As their component fibrils pass outward, toward the aperture in the dura mater, they coalesce into two bundles, receive a tubular sheath from that membrane, and enter the ganglion which is developed upon each root.

The posterior root of the first cervical nerve forms an exception to these characters. It is smaller than the anterior, has frequently no ganglion developed upon it, and when the ganglion exists it is often situated within the dura mater.

Ganglia of the Spinal Nerves.

A **ganglion** is developed upon the posterior root of each of the spinal nerves. These ganglia are of an oval form and of a reddish color; they bear a proportion in size to the nerves upon which they are formed, and are placed in the intervertebral foramina, external to the point where the nerves perforate the dura mater. Each ganglion is bifid internally, where it is joined by the two bundles of the posterior root, the two portions being united into a single mass externally. The ganglion upon the first and second cervical nerves forms an exception to these characters, being placed on the arches of the vertebræ over which the nerves pass. The ganglia, also, of the sacral nerves are placed within the spinal canal; and that on the coccygeal nerve, also in the canal, about the middle of its posterior root.

DISTRIBUTION OF THE SPINAL NERVES.

Immediately beyond the ganglion the two roots coalesce, their fibres intermingle, and the trunk thus formed passes out of the intervertebral foramen, and divides into a posterior division for the supply of the posterior part of the body, and an anterior division for the supply of the anterior part of the body, each containing fibres from both roots.

The **posterior divisions of the spinal nerves** are generally smaller than the anterior; they arise from the trunk resulting from the union of the roots in the intervertebral foramina, and, passing backward, divide into internal and external branches, which are distributed to the muscles and integument behind the spine. The first cervical and lower sacral nerves are exceptions to these characters.

The **anterior divisions of the spinal nerves** supply the parts of the body in front of the spine, including the limbs. They are for the most part larger than the posterior divisions, this increase of size being proportioned to the larger extent of structures they are required to supply. Each division is connected by slender filaments with the sympathetic. In the dorsal region the anterior divisions of the spinal nerves are completely separate from each other, and are uniform in their distribution; but in the cervical, lumbar, and sacral regions they form intricate plexuses previous to their distribution.

Points of Emergence of the Spinal Nerves.

The roots of the spinal nerves from their origin in the cord run obliquely downward to their point of exit from the intervertebral foramina, the amount of obliquity varying in different regions of the spine, and being greater in the lower than the upper part. The level of their emergence from the cord is within certain limits variable, and of course does not correspond to the point of emergence of the nerve from the intervertebral foramina. The accompanying table, from Macalister, shows as accurately as can be shown the relation of these points of origin from the spinal cord to the bodies and spinous processes of the vertebræ:

Level of Body of	No. of Nerve.	Level of tip of Spine of	Level of Body of	No. of Nerve.	Level of tip of Spine of

THE CERVICAL NERVES.

The roots of the cervical nerves increase in size from the first to the fifth, and then remain the same size to the eighth. The posterior roots bear a proportion to the anterior as 3 to 1, which is much greater than in any other region, the individual filaments being also much larger than those of the anterior roots. In direction the roots of the cervical are less oblique than those of the other spinal nerves. The first cervical nerve is directed a little upward and outward; the second is horizontal; the others are directed obliquely downward and outward, the lowest being the most oblique, and consequently longer than the upper, the distance between their place of origin and their point of exit from the spinal canal never exceeding the depth of one vertebra.

The trunk of the first cervical nerve (*suboccipital*) leaves the spinal canal between the occipital bone and the posterior arch of the atlas; the second, between the posterior arch of the atlas and the lamina of the axis; and the eighth (the last), between the last cervical and first dorsal vertebræ.

Each nerve, at its exit from the intervertebral foramen, divides into a posterior and an anterior division. The anterior divisions of the four upper cervical nerves form the cervical plexus. The anterior divisions of the four lower cervical nerves, together with the first dorsal, form the brachial plexus.

Posterior Divisions of the Cervical Nerves (Fig. 456).

The posterior division of the first cervical (*suboccipital*) nerve differs from the posterior divisions of the other cervical nerves in not dividing into an internal and external branch. It is larger than the anterior division, and escapes from the spinal canal between the occipital bone and the posterior arch of the atlas, lying behind the vertebral artery. It enters the suboccipital triangle formed by the Rectus capitis posticus major, the Obliquus superior, and Obliquus inferior, and supplies the Recti and Obliqui muscles, and the Complexus. From the branch which supplies the Inferior oblique a filament is given off which joins the second

cervical nerve. This nerve also occasionally gives off a cutaneous filament, which accompanies the occipital artery and communicates with the occipitalis major and minor nerves.

The posterior division of the second cervical nerve is three or four times greater than the anterior division, and the largest of all the posterior cervical divisions. It emerges from the spinal canal between the posterior arch of the atlas and

FIG. 456.—Posterior divisions of the upper cervical nerves.

lamina of the axis, below the Inferior oblique. It supplies this muscle, and receives a communicating filament from the first cervical. It then divides into an internal and external branch.

The *internal branch*, called, from its size and distribution, the *occipitalis major*, ascends obliquely inward between the Obliquus inferior and Complexus, and pierces the latter muscle and the Trapezius near their attachments to the cranium. It is now joined by a filament from the posterior division of the third cervical nerve, and, ascending on the back part of the head with the occipital artery, divides into two branches, which supply the integument of the scalp as far forward as the vertex, communicating with the occipitalis minor. It gives off an auricular

branch to the back part of the ear and muscular branches to the Complexus. The *external branch* is often joined by the external branch of the posterior division of the third, and supplies the Splenius, Trachelo-mastoid, and Complexus.

The **posterior division of the third cervical** is smaller than the preceding, but larger than the fourth; it differs from the posterior divisions of the remaining cervical nerves in its supplying an additional filament, the third occipital nerve, to the integument of the occiput. The posterior division of the third nerve, like the others, divides into an internal and external branch. The *internal branch* passes between the Complexus and Semispinalis, and, piercing the Splenius and Trapezius, supplies the skin over the latter muscle; the *external branch* joins with that of the posterior division of the second to supply the Splenius, Trachelo-mastoid, and Complexus.

The *third occipital nerve* arises from the internal or cutaneous branch beneath the Trapezius; it then pierces that muscle, and supplies the skin on the lower and back part of the head. It lies to the inner side of the occipitalis major, with which it is connected.

The posterior division of the suboccipital nerve and the internal branches of the posterior divisions of the second and third cervical nerves are occasionally joined beneath the Complexus by communicating branches. This communication is described by Cruveilhier as the *posterior cervical plexus*.

The **posterior divisions of the fourth, fifth, sixth, seventh, and eighth cervical nerves** (Fig. 463) pass backward, and divide, behind the Posterior intertransverse muscles, into internal and external branches. The *internal branches*, the larger, are distributed differently in the upper and lower part of the neck. Those derived from the fourth and fifth nerves pass between the Complexus and Semispinalis muscles, and, having reached the spinous processes, perforate the aponeurosis of the Splenius and Trapezius, and are continued outward to the integument over the Trapezius, whilst those derived from the three lowest cervical nerves are the smallest, and are placed beneath the Semispinalis colli, which they supply, and then pass into the Interspinales, Multifidus spinæ, and Complexus, and send twigs through this latter muscle to supply the integument near the spinous processes (Hirschfeld). The *external branches* supply the muscles at the side of the neck—viz. the Cervicalis ascendens, Transversalis colli, and Trachelo-mastoid.

Anterior Division of the Cervical Nerves.

The **anterior division of the first or suboccipital nerve** is of small size. It escapes from the spinal canal through a groove upon the posterior arch of the atlas. In this groove it lies beneath the vertebral artery, to the inner side of the Rectus capitis lateralis. As it crosses the foramen in the transverse process of the atlas it receives a filament from the sympathetic. It then descends, in front of this process, to communicate with an ascending branch from the second cervical nerve.

Communicating filaments from this nerve join the pneumogastric, the hypoglossal, and sympathetic, and some branches are distributed to the Rectus lateralis and the two Anterior recti. According to Valentin, the anterior division of the suboccipital also distributes filaments to the occipito-atlantal articulation and mastoid process of the temporal bone.

The **anterior division of the second cervical nerve** escapes from the spinal canal, between the posterior arch of the atlas and the lamina of the axis, and, passing forward on the outer side of the vertebral artery, divides in front of the Intertransverse muscle into an ascending branch, which joins the first cervical, and one or two descending branches, which join the third. It gives off the small occipital; a branch to assist in forming the great auricular; another to assist in forming the superficial cervical; one of the communicantes hypoglossi, and a filament to the Sterno-mastoid which communicates in the substance of the muscle with the spinal accessory.

The **anterior division of the third cervical nerve** is double the size of the preceding. At its exit from the intervertebral foramen it passes downward and outward beneath the Sterno-mastoid, and divides into two branches. The ascending branch joins the anterior division of the second cervical; the descending branch passes down in front of the *Scalenus anticus*, and communicates with the fourth. It gives off the greater part of the great auricular and superficial cervical nerves; one of the *communicantes hypoglossi*; a branch to the supraclavicular nerves; a filament to assist in forming the phrenic; and muscular branches to the *Levator anguli scapulæ* and *Trapezius*: this latter nerve communicates beneath the muscle with the spinal accessory. Sometimes the nerve to the *Scalenus medius* is derived from this source.

The **anterior division of the fourth cervical** is of the same size as the preceding. It receives a branch from the third, sends a communicating branch to the fifth cervical, and, passing downward and outward, divides into numerous filaments which cross the posterior triangle of the neck, forming the supraclavicular nerves. It gives a branch to the phrenic nerve whilst it is contained in the intertransverse space, and sometimes a branch to the *Scalenus medius* muscle. It also gives a branch to the *Levator anguli scapulæ* and to the *Trapezius*, which unites with the branch given off from the third nerve, and communicates beneath the muscle with the spinal accessory.

The **anterior divisions of the fifth, sixth, seventh, and eighth cervical nerves** are remarkable for their large size. They are much larger than the preceding nerves, and are all of equal size. They assist in the formation of the brachial plexus.

The Cervical Plexus.

The cervical plexus (Fig. 457) is formed by the anterior divisions of the four upper cervical nerves. It is situated opposite the four upper cervical vertebræ, resting upon the *Levator anguli scapulæ* and *Scalenus medius* muscles, and covered in by the Sterno-mastoid.

Its branches may be divided into two groups, *superficial* and *deep*, which may be thus arranged:

<i>Superficial</i>	{	Ascending .	{	Occipitalis minor.
				Auricularis magnus.
				Superficialis colli.
	{	Descending .	{	Suprasternal.
				Supraclavicular.
				Supra-acromial.
<i>Deep</i> . . .	{	Internal . .	{	Communicating.
				Muscular.
				Communicans hypoglossi.
		External . .	{	Phrenic.
				Communicating.
				Muscular.

Superficial Branches of the Cervical Plexus.

The **Occipitalis minor** (Fig. 463, page 809) arises from the second cervical nerve; it curves round the posterior border of the Sterno-mastoid, and ascends, running parallel to the posterior border of the muscle, to the back part of the side of the head. Near the cranium it perforates the deep fascia, and is continued upward along the side of the head behind the ear, supplying the integument, and communicating with the occipitalis major, the auricularis magnus, and with the posterior auricular branch of the facial.

This nerve gives off an *auricular branch*, which supplies the integument of the upper and back part of the auricle, communicating with the mastoid branch

of the auricularis magnus. This branch is occasionally derived from the great occipital nerve. The occipitalis minor varies in size; it is occasionally double.

The **Auricularis Magnus** is the largest of the ascending branches. It arises from the second and third cervical nerves, winds round the posterior border of the Sterno-mastoid, and, after perforating the deep fascia, ascends upon that muscle beneath the Platysma to the parotid gland, where it divides into facial, auricular, and mastoid branches.

The *facial branches* pass across the parotid, and are distributed to the integument of the face over the parotid gland; others penetrate the substance of the gland and communicate with the facial nerve.

The *auricular branches* ascend to supply the integument of the back part of

FIG. 457.—Plan of the cervical plexus.

the pinna, except at its upper part, communicating with the auricular branches of the facial and pneumogastric nerves.

The *mastoid branch* communicates with the occipitalis minor and the posterior auricular branch of the facial, and is distributed to the integument behind the ear.

The **Superficialis Colli** arises from the second and third cervical nerves, turns round the posterior border of the Sterno-mastoid about its middle, and, passing obliquely forward beneath the external jugular vein to the anterior border of that muscle, perforates the deep cervical fascia, and divides beneath the Platysma into two branches which are distributed to the antero-lateral parts of the neck.

The *ascending branch* gives a filament which accompanies the external jugular vein; it then passes upward to the submaxillary region, and divides into branches, some of which form a plexus with the cervical branches of the facial nerve beneath

the Platysma; others pierce that muscle, supply it, and are distributed to the integument of the upper half of the neck, at its fore part, as high as the chin.

The *descending branch* (occasionally represented by two or more filaments) pierces the Platysma, and is distributed to the integument of the side and front of the neck, as low as the sternum.

The **Descending or supraclavicular branches** arise from the third and fourth cervical nerves: emerging beneath the posterior border of the Sterno-mastoid, they descend in the interval between that muscle and the Trapezius, and divide into branches, which are arranged, according to their position, into three groups.

The *inner or suprasternal branches* cross obliquely over the clavicular and sternal attachments of the Sterno-mastoid, and supply the integument as far as the median line.

The *middle or supraclavicular branches* cross the clavicle, and supply the integument over the Pectoral and Deltoid muscles, communicating with the cutaneous branches of the upper intercostal nerves.

The *external or supra-acromial branches* pass obliquely across the outer surface of the Trapezius and the acromion, and supply the integument of the upper and back part of the shoulder.

Deep Branches of the Cervical Plexus. Internal Series.

The **communicating branches** consist of several filaments which pass from the loop between the first and second cervical nerves in front of the atlas to the pneumogastric, hypoglossal, and sympathetic, and a communicating branch between the fourth and fifth cervical.

Muscular branches supply the Anterior recti and Rectus lateralis muscles; they proceed from the first cervical nerve and from the loop formed between it and the second.

The **Communicans Hypoglossi** (Fig. 455) consists usually of two filaments, one being derived from the second, and the other from the third cervical. These filaments pass downward on the outer side of the internal jugular vein, cross in front of the vein a little below the middle of the neck, and form a loop with the descendens hypoglossi in front of the sheath of the carotid vessels (see page 787). Occasionally, the junction of these nerves takes place within the sheath.

The **Phrenic Nerve** (*internal respiratory of Bell*) arises chiefly from the fourth cervical nerve, with a few filaments from the third and a communicating branch from the fifth. It descends to the root of the neck, running obliquely across the front of the Scalenus anticus, passes over the first part of the subclavian artery, between it and the subclavian vein, and, as it enters the chest, crosses the internal mammary artery near its origin. Within the chest it descends nearly vertically in front of the root of the lung and by the side of the pericardium, between it and the mediastinal portion of the pleura, to the Diaphragm, where it divides into branches, which separately pierce that muscle and are distributed to its under surface.

The two phrenic nerves differ in their length, and also in their relations at the upper part of the thorax.

The *right nerve* is situated more deeply, and is shorter and more vertical in direction than the left; it lies on the outer side of the right vena innominata and superior vena cava.

The *left nerve* is rather longer than the right, from the inclination of the heart to the left side, and from the Diaphragm being lower on this than on the opposite side. At the upper part of the thorax it crosses in front of the arch of the aorta to the root of the lung.

Each nerve supplies filaments to the pericardium and pleura, and near the chest is joined by a filament from the sympathetic, and occasionally by one from the union of the descendens hypoglossi with the spinal nerves: this filament is found, according to Swan, only on the left side. It is also usually connected by

a filament with the nerve to the Subclavius muscle. Branches have been described as passing to the peritoneum.

From the *right nerve* one or two filaments pass to join in a small ganglion with phrenic branches of the solar plexus; and branches from this ganglion are distributed to the hepatic plexus, the suprarenal capsule, and inferior vena cava. From the *left nerve* filaments pass to join the phrenic plexus of the sympathetic, but without any ganglionic enlargement.

Deep Branches of the Cervical Plexus. External Series.

Communicating Branches.—The deep branches of the external series of the cervical plexus communicate with the spinal accessory nerve, in the substance of the Sterno-mastoid muscle, in the occipital triangle, and beneath the Trapezius.

Muscular branches are distributed to the Sterno-mastoid, Trapezius, Levator anguli scapulæ, and Scalenus medius.

The branch for the Sterno-mastoid is derived from the second cervical; the Trapezius and Levator anguli scapulæ receive branches from the third and fourth. The Scalenus medius is supplied sometimes from the third, sometimes the fourth, and occasionally from both nerves.

The Brachial Plexus (Fig. 458).

The **Brachial Plexus** is formed by the union of the anterior branches of the four lower cervical and the greater part of the first dorsal nerves, receiving also a fasciculus from the fourth cervical nerve. It extends from the lower part of the side of the neck to the axilla. It is very broad, and presents little of a plexiform arrangement at its commencement. It is narrow opposite the clavicle, becomes broad and forms a more dense interlacement in the axilla, and divides opposite the coracoid process into numerous branches for the supply of the upper limb. The nerves which form the plexus are all similar in size, and their mode of communication is subject to considerable variation, so that no one plan can be given as applying to every case. The following appears, however, to be the most constant arrangement: the fifth and sixth cervical unite together soon after their exit from the intervertebral foramina to form a common trunk. The eighth cervical and first dorsal also unite to form one trunk. So that the nerves forming the plexus, as they lie on the Scalenus medius external to the outer border of the Scalenus anticus, are blended into three trunks—an outer one, formed by the junction of the fifth and sixth cervical nerves; a middle one, consisting of the seventh cervical nerve; and an inner one, formed by the junction of the eighth cervical and first dorsal nerves. As they pass beneath the clavicle, each of these three trunks divides into two branches, an *anterior* and a *posterior*. The anterior divisions of the outer and middle trunks then unite to form a common cord, which is situated on the outer side of the middle part of the axillary artery, and is called the *outer cord* of the brachial plexus. The anterior division of the inner trunk, formed by the union of the eighth cervical and first dorsal, passes down on the inner side of the axillary artery in the middle of the axilla, and forms the *inner cord* of the brachial plexus. The posterior divisions of the outer trunk (formed by the junction of the fifth and sixth nerves) and of the middle trunk (the seventh nerve) unite together to form the *posterior cord* of the brachial plexus, which is situated behind the second portion of the axillary artery. From this posterior cord are given off the two lower subscapular nerves, the upper subscapular nerve being given off from the posterior division of the outer trunk prior to its junction with the posterior division of the middle trunk. The posterior cord divides into the circumflex and musculo-spiral nerves. The musculo-spiral nerve is subsequently joined by the posterior division of the inner trunk, formed by the union of the eighth cervical and first dorsal.

The brachial plexus communicates with the cervical plexus by a branch from the fourth to the fifth nerve, and with the phrenic nerve by a branch from the fifth cervical, which joins that nerve on the Anterior scalenus muscle: the cervi-

cal and first dorsal nerves are also joined by filaments from the middle and inferior cervical ganglia of the sympathetic, close to their exit from the intervertebral foramina.

Relations.—*In the neck* the brachial plexus lies at the first between the Anterior and Middle scaleni muscles, and then above and to the outer side of the subclavian artery: it then passes behind the clavicle and Subclavius muscle, lying upon the first serration of the Serratus magnus, and the Subscapularis muscles. *In the axilla* it is placed on the outer side of the first portion of the axillary artery; it

FIG. 458.—Plan of the brachial plexus.

surrounds the artery in the second part of its course, one cord lying upon the outer side of that vessel, one on the inner side, and one behind it, and at the lower part of the axillary space gives off its terminal branches to the upper extremity.

Branches.—The branches of the brachial plexus are arranged in two groups—viz. those given off above the clavicle, and those below that bone.

Branches above the Clavicle.

Communicating.
Muscular.

Posterior thoracic.
Suprascapular.

The communicating branch with the phrenic is derived from the fifth cervical nerve or from the loop between the fifth and sixth; it joins the phrenic on the Anterior scalenus muscle.

The muscular branches supply the Longus colli, Scaleni, Rhomboidei, and Subclavius muscles. Those for the Longus colli and Scaleni arise from the lower

cervical nerves at their exit from the intervertebral foramina. The Rhomboid branch arises from the fifth cervical, pierces the *Scalenus medius*, and passes beneath the *Levator anguli scapulæ*, which it occasionally supplies, to the Rhomboid muscles. The nerve to the *Subclavius* is a small filament which arises from the

FIG. 459.—Cutaneous nerves of right upper extremity. Anterior view.

FIG. 460.—Cutaneous nerves of right upper extremity. Posterior view.

fifth cervical at its point of junction with the sixth nerve; it descends in front of the subclavian artery to the *Subclavius* muscle, and is usually connected by a filament with the phrenic nerve.

The **posterior thoracic nerve** (*long thoracic, external respiratory of Bell*) (Fig. 461) supplies the *Serratus magnus*, and is remarkable for the length of its course. It sometimes arises by two roots from the fifth and sixth cervical nerves

FIG. 461.—Nerves of the left upper extremity.

immediately after their exit from the intervertebral foramina, but generally by three roots from the fifth, sixth, and seventh nerves. These unite in the substance

of the Middle scalenus muscle, and, after emerging from it, the nerve passes down behind the brachial plexus and the axillary vessels, resting on the outer surface of the Serratus magnus. It extends along the side of the chest to the lower border of that muscle, supplying filaments to each of its digitations.

The **suprascapular nerve** (Fig. 462) arises from the cord formed by the fifth and sixth cervical nerves; passing obliquely outward beneath the Trapezius, it enters the supraspinous fossa, through the notch in the upper border of the scapula, and, passing beneath the Supraspinatus muscle, curves in front of the spine of the scapula to the infraspinous fossa. In the supraspinous fossa it gives off two branches to the Supraspinatus muscle, and an articular filament to the shoulder-joint; and in the infraspinous fossa it gives off two branches to the Infraspinatus muscle, besides some filaments to the shoulder-joint and scapula.

Branches below the Clavicle.

The branches given off below the clavicle are derived from the three cords of the brachial plexus, in the following manner:

From the outer cord arise the external of the two anterior thoracic nerves, the musculo-cutaneous nerve, and the outer head of the median.

From the inner cord arise the internal of the two anterior thoracic nerves, the internal cutaneous, the lesser internal cutaneous (nerve of Wrisberg), the ulnar, and inner head of the median.

From the posterior cord arise two of the three subscapular nerves, the third arising from the posterior division of the trunk formed by the fifth and sixth cervical nerves; the cord then divides into the musculo-spiral and circumflex nerves.

These may be arranged according to the parts they supply:

To the chest	Anterior thoracic.
To the shoulder	{ Subscapular.
	{ Circumflex.
	{ Musculo-cutaneous.
	{ Internal cutaneous.
To the arm, forearm, and hand .	{ Lesser internal cutaneous.
	{ Median.
	{ Ulnar.
	{ Musculo-spiral.

The fasciculi of which these nerves are composed may be traced through the plexus to the spinal nerves from which they originate. They are as follows:

External anterior thoracic	from 5th, 6th, and 7th cervical.
Internal anterior thoracic	" 8th cervical and 1st dorsal.
Subscapular	" 5th, 6th, 7th, and 8th cervical.
Circumflex	" 5th, 6th, 7th, and 8th cervical.
Musculo-cutaneous	" 5th, 6th, and 7th cervical.
Internal cutaneous	" 8th cervical and 1st dorsal.
Lesser internal cutaneous	" 1st dorsal.
Median	" 6th, 7th, and 8th cervical, and 1st dorsal.
Ulnar	" 8th cervical and 1st dorsal.
Musculo-spiral	" 6th, 7th, and 8th cervical, and 1st dorsal.

The **Anterior Thoracic Nerves** (Fig. 461), two in number, supply the Pectoral muscles.

The *external* or superficial nerve, the larger of the two, arises from the outer cord of the brachial plexus, through which its fibres may be traced to the fifth, sixth, and seventh cervical nerves. It passes inward, across the axillary artery and vein, pierces the costo-coracoid membrane, and is distributed to the under surface of the Pectoralis major. It sends down a communicating filament to join

the internal nerve, which forms a loop round the inner side of the axillary artery.

The *internal* or deep nerve arises from the inner cord, and through it from the eighth cervical and first dorsal. It passes upward between the axillary artery and vein, and joins with the filament from the superficial nerve. It then passes to the under surface of the Pectoralis minor muscle, where it divides into a number of branches, which supply the muscle on its under surface. Some of the branches pass through the muscle; others wind round its upper border and pierce the costo-coracoid membrane to supply the Pectoralis major.

The **Subscapular Nerves**, three in number, supply the Subscapularis, Teres major, and Latissimus dorsi muscles. The fasciculi of which they are composed may be traced to the fifth, sixth, seventh, and eighth cervical nerves.

The *upper subscapular nerve*, the smallest, enters the upper part of the Subscapularis muscle.

The *lower subscapular nerve* enters the axillary border of the Subscapularis and terminates in the Teres major. The latter muscle is sometimes supplied by a separate branch.

The *middle* or *long subscapular*, the largest of the three, follows the course of the subscapular artery, along the posterior wall of the axilla to the Latissimus dorsi, through which it may be traced as far as its lower border.

The **Circumflex Nerve** (Fig. 462) supplies some of the muscles and the integument of the shoulder and the shoulder-joint. It arises from the posterior cord of the brachial plexus, in common with the musculo-spiral nerve, and its fibres may be traced through the posterior cord to the fifth, sixth, seventh, and eighth cervical nerves. It is at first placed behind the axillary artery, between it and the Subscapularis muscle, and passes downward and outward to the lower border of that muscle. It then winds backward in company with the posterior circumflex artery, through a quadrilateral space bounded above by the Teres minor, below by the Teres major, internally by the long head of the Triceps, and externally by the neck of the humerus, and divides into two branches.

The *upper branch* winds round the surgical neck of the humerus, beneath the Deltoid, with the posterior circumflex vessels, as far as the anterior border of that muscle, supplying it, and giving off cutaneous branches, which pierce the muscle and ramify in the integument covering its lower part.

The *lower branch*, at its origin, distributes filaments to the Teres minor and back part of the Deltoid muscles. Upon the filament to the former muscle a gangliform enlargement usually exists. The nerve then pierces the deep fascia, and supplies the integument over the lower two-thirds of the posterior surface of the Deltoid, as well as that covering the long head of the Triceps.

The circumflex nerve, before its division, gives off an articular filament, which enters the shoulder-joint below the Subscapularis.

The **Musculo-cutaneous Nerve** (Fig. 461) (*external cutaneous* or *perforans Casserii*)¹ supplies some of the muscles of the arm and the integument of the forearm. It arises from the outer cord of the brachial plexus, opposite the lower border of the Pectoralis minor, receiving filaments from the fifth, sixth, and seventh cervical nerves. It perforates the Coraco-brachialis muscle, passes obliquely between the Biceps and Brachialis anticus to the outer side of the arm, and, a little above the elbow, winds round the outer border of the tendon of the Biceps, and, perforating the deep fascia, becomes cutaneous. This nerve in its course through the arm supplies the Coraco-brachialis, Biceps, and part of the Brachialis anticus muscles. It sends a small branch to the bone, which enters the nutrient foramen with the accompanying artery and a filament, from the branch supplying the Brachialis anticus, to the elbow-joint.

The cutaneous portion of the nerve passes behind the median cephalic vein, and divides, opposite the elbow-joint, into an anterior and a posterior branch.

The *anterior branch* descends along the radial border of the forearm to the

¹ See foot-note, page 759.

wrist, and supplies the integument over the outer half of the anterior surface. At the wrist-joint it is placed in front of the radial artery, and some filaments, piercing the deep fascia, accompany that vessel to the back of the wrist, supplying the carpus. The nerve then passes downward to the ball of the thumb, where it terminates in cutaneous filaments. It communicates with a branch from the radial nerve and the palmar cutaneous branch of the median.

The *posterior branch* passes downward along the back part of the radial side of the forearm to the wrist. It supplies the integument of the lower third of the forearm, communicating with the radial nerve and the external cutaneous branch of the musculo-spiral.

The **Internal Cutaneous Nerve** (Fig. 461) is one of the smallest branches of the brachial plexus. It arises from the inner cord in common with the ulnar and internal head of the median, and at its commencement is placed on the inner side of the brachial artery. It derives its fibres from the eighth cervical and first dorsal nerves. It passes down the inner side of the arm, pierces the deep fascia with the basilic vein, about the middle of the limb, and, becoming cutaneous, divides into two branches, anterior and posterior.

This nerve gives off, near the axilla, a cutaneous filament, which pierces the fascia and supplies the integument covering the Biceps muscle nearly as far as the elbow. This filament lies a little external to the common trunk, from which it arises.

The *anterior branch*, the larger of the two, passes usually in front of, but occasionally behind, the median basilic vein. It then descends on the anterior surface of the ulnar side of the forearm, distributing filaments to the integument as far as the wrist, and communicating with a cutaneous branch of the ulnar nerve.

The *posterior branch* passes obliquely downward on the inner side of the basilic vein, passes in front of, or over, the internal condyle of the humerus to the back of the forearm, and descends on the posterior surface of its ulnar side as far as the wrist, distributing filaments to the integument. It communicates, above the elbow, with the lesser internal cutaneous, and above the wrist with the dorsal cutaneous branch of the ulnar nerve (Swan).

The **Lesser Internal Cutaneous Nerve** (*nerve of Wrisberg*) (Fig. 461) is distributed to the integument on the inner side of the arm. It is the smallest of the branches of the brachial plexus, and, arising from the inner cord with the internal cutaneous and ulnar nerves, receives its fibres from the first dorsal nerve. It passes through the axillary space, at first lying behind, and then on the inner side of, the axillary vein, and communicates with the intercosto-humeral nerve. It descends along the inner side of the brachial artery to the middle of the arm, where it pierces the deep fascia, and is distributed to the integument of the back part of the lower third of the arm, extending as far as the elbow, where some filaments are lost in the integument in front of the inner condyle, and others over the olecranon. It communicates with the posterior branch of the internal cutaneous nerve.

In some cases the nerve of Wrisberg and intercosto-humeral are connected by two or three filaments which form a plexus at the back part of the axilla. In other cases the intercosto-humeral is of large size, and takes the place of the nerve of Wrisberg, receiving merely a filament of communication from the brachial plexus, which represents the latter nerve. In other cases this filament is wanting, the place of the nerve of Wrisberg being supplied entirely from the intercosto-humeral.

The **Median Nerve** (Fig. 461) has received its name from the course it takes along the middle of the arm and forearm to the hand, lying between the ulnar and the musculo-spiral and radial nerves. It arises by two roots, one from the outer, and one from the inner, cord of the brachial plexus; these embrace the lower part of the axillary artery, uniting either in front or on the outer side of that vessel. It receives filaments from the sixth, seventh, and eighth cervical and the

first dorsal. As it descends through the arm, it lies at first on the outer side of the brachial artery, crosses that vessel in the middle of its course, usually in front, but occasionally behind it, and lies on its inner side to the bend of the elbow, where it is placed beneath the bicipital fascia, and is separated from the elbow-joint by the Brachialis anticus. *In the forearm* it passes between the two heads of the Pronator radii teres, and descends beneath the Flexor sublimis, lying on the Flexor profundus, to within two inches above the annular ligament, where it becomes more superficial, lying between the tendons of the Flexor sublimis and Flexor carpi radialis, beneath, or rather to the ulnar side of, the tendon of the Palmaris longus, covered by the integument and fascia. It then passes beneath the annular ligament into the hand. In its course through the forearm it is accompanied by a small artery.

Branches.—No branches are given off from the median nerve in the arm. *In the forearm* its branches are muscular, anterior interosseous, and palmar cutaneous, and, according to Rudinger and Macalister, two articular twigs to the elbow-joint.

The *muscular branches* supply all the superficial muscles on the front of the forearm, except the Flexor carpi ulnaris. These branches are derived from the nerve near the elbow. The branch furnished to the Pronator radii teres often arises above the joint.

The *anterior interosseous* supplies the deep muscles on the front of the forearm, except the inner half of the Flexor profundus digitorum. It accompanies the anterior interosseous artery along the interosseous membrane, in the interval between the Flexor longus pollicis and Flexor profundus digitorum muscles, both of which it supplies, and terminates below in the Pronator quadratus.

The *palmar cutaneous branch* arises from the median nerve at the lower part of the forearm. It pierces the fascia above the annular ligament, and, descending over that ligament, divides into two branches; of which the *outer* supplies the skin over the ball of the thumb, and communicates with the anterior cutaneous branch of the musculo-cutaneous nerve; and the *inner* supplies the integument of the palm of the hand, communicating with the cutaneous branch of the ulnar.

In the palm of the hand the median nerve is covered by the integument and palmar fascia and crossed by the superficial palmar arch. It rests upon the tendons of the flexor muscles. In this situation it becomes enlarged, somewhat flattened, of a reddish color, and divides into two branches. Of these, the *external* supplies a muscular branch to some of the muscles of the thumb and digital branches to the thumb and index finger; the *internal* supplies digital branches to the contiguous sides of the index and middle and of the middle and ring fingers.

The *branch to the muscles of the thumb* is a short nerve which subdivides to supply the Abductor, Opponens, and outer head of the Flexor brevis pollicis muscles, the remaining muscles of this group being supplied by the ulnar nerve.

The *digital branches* are five in number. The *first* and *second* pass along the borders of the thumb, the external branch communicating with branches of the radial nerve. The *third* passes along the radial side of the index finger, and supplies the First lumbricalis muscle. The *fourth* subdivides to supply the adjacent sides of the index and middle fingers, and sends a branch to the Second lumbrical muscle. The *fifth* supplies the adjacent sides of the middle and ring fingers, and communicates with a branch from the ulnar nerve.

Each digital nerve, opposite the base of the first phalanx, gives off a dorsal branch, which joins the dorsal digital nerve from the radial and runs along the side of the dorsum of the finger, to end in the integument over the last phalanx. At the end of the finger the digital nerve divides into a palmar and a dorsal branch, the former of which supplies the extremity of the finger, and the latter ramifies round and beneath the nail. The digital nerves, as they run along the fingers, are placed superficial to the digital arteries.

The **Ulnar Nerve** (Fig. 461) is placed along the inner or ulnar side of the upper limb, and is distributed to the muscles and integument of the forearm and hand. It is smaller than the median, behind which it is placed, diverging from it in its course down the arm. It arises from the inner cord of the brachial plexus, in common with the inner head of the median and the internal cutaneous nerve, and derives its fibres from the eighth cervical and first dorsal nerves. At its commencement it lies at the inner side of the axillary artery, and holds the same relation with the brachial artery to the middle of the arm. From this point it runs obliquely across the internal head of the Triceps, pierces the internal intermuscular septum, and descends to the groove between the internal condyle and the olecranon, accompanied by the inferior profunda artery. *At the elbow* it rests upon the back of the inner condyle, and passes into the forearm between the two heads of the Flexor carpi ulnaris. *In the forearm* it descends in a perfectly straight course along its ulnar side, lying upon the Flexor profundus digitorum, its upper half being covered by the Flexor carpi ulnaris, its lower half lying on the outer side of the muscle, covered by the integument and fascia. The ulnar artery, in the upper third of its course, is separated from the ulnar nerve by a considerable interval, but in the rest of its extent the nerve lies to its inner side. *At the wrist* the ulnar nerve crosses the annular ligament on the outer side of the pisiform bone, to the inner side and a little behind the ulnar artery, and immediately beyond this bone divides into two branches, superficial and deep palmar.

The branches of the ulnar nerve are—

In the forearm	{	Articular (elbow).	In the hand	{	Superficial palmar.
		Muscular.			Deep palmar.
		Cutaneous.			
		Dorsal cutaneous.			
		Articular (wrist).			

The *articular branches* distributed to the elbow-joint consist of several small filaments. They arise from the nerve as it lies in the groove between the inner condyle and olecranon.

The *muscular branches* are two in number—one supplying the Flexor carpi ulnaris; the other, the inner half of the Flexor profundus digitorum. They arise from the trunk of the nerve near the elbow.

The *cutaneous branch* arises from the ulnar nerve about the middle of the forearm, and divides into two branches.

One branch (frequently absent) pierces the deep fascia near the wrist, and is distributed to the integument, communicating with a branch of the internal cutaneous nerve.

The second branch (*palmar cutaneous*) lies on the ulnar artery, which it accompanies to the hand, some filaments entwining round the vessel; it ends in the integument of the palm, communicating with branches of the median nerve.

The *dorsal cutaneous branch* arises about two inches above the wrist; it passes backward beneath the Flexor carpi ulnaris, perforates the deep fascia, and, running along the ulnar side of the back of the wrist and hand, supplies the inner side of the little finger and the adjoining sides of the little and ring fingers; it communicates with the posterior branch of the internal cutaneous nerve, and sends a communicating filament to that branch of the radial nerve which supplies the adjoining sides of the middle and ring fingers.

The *articular filaments to the wrist* are also supplied by the ulnar nerve.

The *superficial palmar branch* supplies the Palmaris brevis and the integument on the inner side of the hand, and terminates in two digital branches, which are distributed, one to the ulnar side of the little finger, the other to the adjoining sides of the little and ring fingers, the latter communicating with a branch from the median. The digital branches are distributed to the fingers in the same manner as the digital branches of the median.

The *deep palmar branch* passes between the Abductor and Flexor brevis

minimi digiti muscles, and follows the course of the deep palmar arch beneath the flexor tendons. At its origin it supplies the muscles of the little finger. As it crosses the deep part of the hand it sends two branches to each interosseous space, one for the Dorsal and one for the Palmar interosseous muscle, the branches to the Second and Third palmar interossei supplying filaments to the two inner Lumbrical muscles. At its termination between the thumb and index finger it supplies the Adductores transversus et obliquus pollicis and the inner head of the Flexor brevis pollicis.

It will be remembered that the inner part of the Flexor profundus digitorum is supplied by the ulnar nerve; the two inner Lumbricales, which are connected with the tendons of this part of the muscle, are therefore supplied by the same nerve. The outer part of the Flexor profundus is supplied by the median nerve; the two outer Lumbricales, which are connected with the tendons of this part of the muscle, are therefore supplied by the same nerve.

The **Musculo-spiral Nerve** (Fig. 462), the largest branch of the brachial plexus, supplies the muscles of the back part of the arm and forearm and the integument of the same parts, as well as that of the back of the hand. It arises from the posterior cord of the brachial plexus by a common trunk with the circumflex nerve, and is afterward joined by the posterior division of the trunk, formed by the junction of the eighth cervical and first dorsal nerves. It receives filaments from the sixth, seventh, and eighth cervical and first dorsal nerves. At its commencement it is placed behind the axillary and upper part of the brachial arteries, passing down in front of the tendons of the Latissimus dorsi and Teres major. It winds round the humerus in the musculo-spiral groove with the superior profunda artery, passing from the inner to the outer side of the bone, between the internal and external heads of the Triceps muscle. It pierces the external intermuscular septum, and descends between the Brachialis anticus and Supinator longus to the front of the external condyle, where it divides into the radial and posterior interosseous nerves.

The branches of the musculo-spiral nerve are—

Muscular.	Radial.
Cutaneous.	Posterior interosseous.

The *muscular branches* are divided into internal, posterior, and external; they supply the Triceps, Anconeus, Supinator longus, Extensor carpi radialis longior, and Brachialis anticus. These branches are derived from the nerve at the inner side, back part, and outer side of the arm.

The internal muscular branches supply the inner and middle heads of the Triceps muscle. That to the inner head of the Triceps is a long, slender filament which lies close to the ulnar nerve, as far as the lower third of the arm, and is often intimately connected with it.

The posterior muscular branch, of large size, arises from the nerve in the groove between the Triceps and the humerus. It divides into branches which supply the outer head of the Triceps and Anconeus muscles. The branch for the latter muscle is a long, slender filament which descends in the substance of the Triceps to the Anconeus.

The external muscular branches supply the Supinator longus, Extensor carpi radialis longior, and (usually) the outer part of the Brachialis anticus.

The *cutaneous branches* are three in number, one internal and two external.

The internal cutaneous branch arises in the axillary space with the inner muscular branch. It is of small size, and passes through the axilla to the inner side of the arm, supplying the integument on its posterior aspect nearly as far as the olecranon. In its course it crosses beneath the intercosto-humeral, with which it communicates.

The two external cutaneous branches perforate the outer head of the Triceps at its attachment to the humerus. The upper and smaller one passes to the front of the elbow, lying close to the cephalic vein, and supplies the integu-

ment of the lower half of the arm on its anterior aspect. The lower branch pierces the deep fascia below the insertion of the Deltoid, and passes down along

FIG. 462.—The suprascapular, circumflex, and musculo-spiral nerves.

side of the index finger; the second, the adjoining sides of the index and middle fingers; and the third, the adjacent borders of the middle and ring fingers.¹ The latter nerve communicates with a filament from the dorsal branch of the ulnar nerve.

¹ According to Hutchinson, the digital nerve to the thumb reaches only as high as the root of the nail; the one to the forefinger as high as the middle of the second phalanx; and the one to the middle and ring fingers not higher than the first phalangeal joint (*London Hosp. Gaz.* vol. iii. p. 319.)

the outer side of the arm and elbow, and then along the back part of the radial side of the forearm to the wrist, supplying the integument in its course, and joining, near its termination, with the posterior cutaneous branch of the musculo-cutaneous nerve.

The **radial nerve** passes along the front of the radial side of the forearm to the commencement of its lower third. It lies at first a little to the outer side of the radial artery, concealed beneath the Supinator longus. In the middle third of the forearm it lies beneath the same muscle, in close relation with the outer side of the artery. It quits the artery about three inches above the wrist, passes beneath the tendon of the Supinator longus, and, piercing the deep fascia at the outer border of the forearm, divides into two branches.

The external branch, the smaller of the two, supplies the integument of the radial side and ball of the thumb, joining with the anterior branch of the musculo-cutaneous nerve.

The internal branch communicates, above the wrist, with the posterior cutaneous branch from the musculo-cutaneous, and on the back of the hand forms an arch with the dorsal cutaneous branch of the ulnar nerve. It then divides into three digital nerves, which are distributed as follows: The first supplies the ulnar side of the thumb and the radial

The **Posterior Interosseous Nerve** winds to the back of the forearm through the fibres of the *Supinator brevis*, and passes down, between the superficial and deep layer of muscles, to the middle of the forearm. Considerably diminished in size, it descends on the interosseous membrane, beneath the *Extensor longus pollicis*, to the back of the carpus, where it presents a gangliform enlargement from which filaments are distributed to the ligaments and articulations of the carpus. It supplies all the muscles of the radial and posterior brachial regions, excepting the *Anconeus*, *Supinator longus*, and *Extensor carpi radialis longior*.

Surgical Anatomy.—The brachial plexus may be ruptured by traction on the limb leading to complete paralysis. In these cases the lesion would appear to be rather a tearing away of the nerves from the spinal cord than a solution of continuity of the nerve-fibres themselves. In the axilla any of the nerves forming the brachial plexus may be injured in a wound of this part, the median being the one which is most frequently damaged from its exposed position, and the musculo-spiral, on account of its sheltered and deep position, being the least often wounded. The brachial plexus in the axilla is often damaged from the pressure of a crutch, producing the condition known as "crutch paralysis." In these cases the musculo-spiral appears to be the nerve which is most frequently implicated to the greatest extent, the ulnar nerve being the one that appears to suffer next in frequency.

The *circumflex nerve* is of particular surgical interest. On account of its course round the joint it is liable to be torn in fractures of the surgical neck of the humerus and in dislocations of the shoulder-joint, leading to paralysis of the deltoid, and, according to Erb, inflammation of the shoulder-joint is liable to be followed by a neuritis of this nerve from extension of the inflammation to it.

Mr. Hilton takes the circumflex nerve as an illustration of a law which he lays down, that "the same trunks of nerves whose branches supply the groups of muscles moving a joint furnish also a distribution of nerves to the skin over the insertions of the same muscles, and the interior of the joint receives its nerves from the same source." In this way he explains the fact that an inflamed joint becomes rigid, because the same nerves which supply the interior of the joint supply the muscles also which move that joint.

The *median nerve* is liable to injury in wounds of the forearm. When paralyzed, there is loss of flexion of the second phalanges of all the fingers and of the terminal phalanges of the index and middle fingers. Flexion of the terminal phalanges of the ring and middle fingers is effected by that portion of the *Flexor profundus digitorum* which is supplied by the ulnar nerve. There is power to flex the proximal phalanges through the *Interossei*. The thumb cannot be flexed or opposed, and is maintained in a position of extension and adduction. All power of pronation is lost. The wrist can be flexed, if the hand is first adducted, by the action of the *Flexor carpi ulnaris*. There is loss or impairment of sensation on the palmar surface of the thumb, index, middle, and outer half of the ring fingers, and on the dorsal surface of the same fingers over the last two phalanges; except in the thumb, where the loss of sensation would be limited to the back of the last phalanx. In order to expose the median nerve for the purpose of stretching an incision should be made along the ulnar side of the tendon of the *Palmaris longus*, which serves as a guide to the nerve.

The *ulnar nerve* is also liable to be injured in wounds of the forearm. When paralyzed, there is loss of power of flexion in the ring and little fingers; there is impaired power of ulnar flexion and adduction; there is inability to spread out the fingers from paralysis of the *Interossei*; and there is inability to adduct the thumb. Sensation is lost or impaired in the skin supplied by the nerve. In order to expose the nerve in the lower part of the forearm, an incision should be made along the outer border of the tendon of the *Flexor carpi ulnaris*, and the nerve will be found lying on the ulnar side of the ulnar artery.

The *musculo-spiral nerve* is probably more frequently injured than any other nerve of the upper extremity. In consequence of its close relationship to the humerus as it lies in the musculo-spiral groove, it is frequently torn or injured in fractures of this bone, or subsequently involved in the callus that may be thrown out around a fracture, and thus pressed upon and its functions interfered with. It is also liable to be contused against the bone by kicks or blows or to be divided by wounds of the arm. When paralyzed, the hand is flexed at the wrist and lies flaccid. This is known as "drop-wrist." The fingers are also flexed, and on an attempt being made to extend them the last two phalanges only will be extended through the action of the *Interossei*, the first phalanges remaining flexed. There is no power of extending the wrist. Supination is completely lost when the forearm is extended on the arm, but it is possible to a certain extent if the forearm is flexed so as to allow of the action of the *Biceps*. The power of extension of the forearm is lost on account of paralysis of the *Triceps*. The best position in which to expose the nerve for the purpose of stretching is to make an incision along the inner border of the *Supinator longus*, just above the level of the elbow-joint. The skin and superficial structures are to be divided and the deep fascia exposed. The white line in this structure indicating the border of the muscle is to be defined, and the deep fascia divided in this line. By now raising the *Supinator longus* the nerve will be found lying beneath it, on the *Brachialis anticus*.

THE DORSAL NERVES (Fig. 463).

The **Dorsal Nerves** are twelve in number on each side. The first appears between the first and second dorsal vertebræ, and the last between the last dorsal and first lumbar.

The *roots of the dorsal nerves* are of small size, and vary but slightly from the second to the last. Both roots are very slender, the posterior roots only slightly exceeding the anterior in thickness. They gradually increase in length from above downward, and pass down in contact with the spinal cord for a distance equal to the height of, at least, two vertebræ, in the lower part of the dorsal region, before they emerge from the spinal canal. They then join in the intervertebral foramen, and at their exit divide into two primary divisions, a posterior (dorsal) and an anterior (intercostal).

The first and last dorsal nerves are peculiar in some respects.

Posterior Divisions of the Dorsal Nerves.

The **posterior divisions of the dorsal nerves**, which are smaller than the anterior, pass backward between the transverse processes, and divide into internal and external branches.

The *internal branches of the six upper nerves* pass inward between the *Semispinalis dorsi* and *Multifidus spinæ* muscles, which they supply, and then, piercing the origins of the *Rhomboidei* and *Trapezius* muscles, become cutaneous by the side of the spinous processes and ramify in the integument. The internal branches of the six lower nerves are distributed to the *Multifidus spinæ*, without giving off any cutaneous filaments.

The *external branches* increase in size from above downward. They pass through the *Longissimus dorsi* to the cellular interval between it and the *Iliocostalis*, and supply those muscles, as well as their continuations upward to the head, and the *Levatores costarum*; the five or six lower nerves also give off cutaneous filaments, which pierce the *Serratus posticus inferior* and *Latissimus dorsi* in a line with the angles of the ribs, and then ramify in the integument.

The *cutaneous branches of the dorsal nerves* are twelve in number. The six upper cutaneous nerves are derived from the internal branches of the posterior divisions of the dorsal nerves. They pierce the origins of the *Rhomboidei* and *Trapezius* muscles, and become cutaneous by the side of the spinous processes, and then ramify in the integument. They are frequently furnished with gangliform enlargements. The six lower cutaneous nerves are derived from the external branches of the posterior divisions of the dorsal nerves. They pierce the *Serratus posticus inferior* and *Latissimus dorsi* in a line with the angles of the ribs, and then ramify in the integument.

Anterior Divisions of the Dorsal Nerves.

The **anterior divisions of the dorsal nerves** (*intercostal nerves*) are twelve in number on each side. They are, for the most part, distributed to the parietes of the thorax and abdomen, separately from each other, without being joined in a plexus; in which respect they differ from the other spinal nerves. Each nerve is connected with the adjoining ganglia of the sympathetic by one or two filaments. The intercostal nerves may be divided into two sets, from the difference they present in their distribution. The six upper, with the exception of the first and the intercosto-humeral branch of the second, are limited in their distribution to the parietes of the chest. The six lower supply the parietes of the chest and abdomen, the last one sending a cutaneous filament to the hip.

The First Dorsal Nerve.—The anterior division of the first dorsal nerve divides into two branches: one, the larger, leaves the thorax in front of the neck of the first rib, and enters into the formation of the brachial plexus; the other and smaller branch runs along the first intercostal space, forming the *first intercostal nerve*, and terminates on the front of the chest by forming the first anterior

FIG. 463.—Superficial and deep distribution of the posterior branches of the spinal nerves (after Hirschfeld and Leveillé). On the left side the cutaneous branches are represented lying on the superficial layer of muscles. On the right side the superficial muscles have been removed, the Splenius capitis and Complexus divided in the neck, and the Erector spinae divided and partly removed in the back, so as to expose the posterior divisions of the spinal nerves near their origin. *a a*. Lesser occipital nerve from the cervical plexus. 1. External muscular branches of the first cervical nerve, and union by a loop with the second. 2. External branch from the posterior division of the third nerve. 3. Its internal branch, sometimes called the third occipital. 4' to 8'. The internal branches of the several corresponding nerves on the left side. The external branches of these nerves, proceeding to muscles, are displayed on the right side, *d 1* to *d 6*, and thence to *d 12*. External muscular branches of the posterior divisions of the twelve dorsal nerves on the right side, *d 1'* to *d 6'*. The internal cutaneous branches of the six lower dorsal nerves on the left side, *d 7'* to *d 12'*. Cutaneous twigs from the external branches of the six lower dorsal nerves. *l l*. External branches from the posterior divisions of several lumbar nerves on the right side, piercing the muscles, the lower descending over the gluteal region. *l l'*. The same, more superficially, on the left side. *s s*. The issue and union by loops of the posterior divisions of four sacral nerves on the right side. *s' s'*. Some of those distributed to the skin on the left side.

cutaneous nerve of the thorax. Occasionally this anterior cutaneous branch is wanting. The first intercostal nerve, as a rule, gives off no lateral cutaneous

branch, but sometimes a small branch is given off which communicates with the intercosto-humeral.

The Upper Dorsal Nerves.—The anterior divisions of the second, third, fourth, fifth, and sixth dorsal nerves and the small branch from the first dorsal are confined to the parietes of the thorax, and are named *upper* or *pectoral intercostal nerves*. They pass forward in the intercostal spaces with the intercostal vessels, being situated below them. At the back of the chest they lie between the pleura and the External intercostal muscle, but are soon placed between the two planes of Intercostal muscles as far as the middle of the rib. They then enter the substance of the Internal intercostal muscles, and, running amidst their fibres as far as the costal cartilages, they gain the inner surface of the muscles and lie between them and the pleura. Near the sternum they cross the internal mammary artery and Triangularis sterni muscle, pierce the Internal intercostal and Pectoralis major muscles, and supply the integument of the front of the chest and over the mammary gland, forming the anterior cutaneous nerves of the thorax, the branch from the second nerve becoming joined with the supraclavicular nerves of the cervical plexus.

Branches.—Numerous slender muscular filaments supply the Intercostals, the Infracostales, the Levatores costarum, Serratus posticus superior, and Triangularis sterni muscles. Some of these branches, at the front of the chest, cross the costal cartilages from one to another intercostal space.

Lateral Cutaneous Nerves.—These are derived from the intercostal nerves, midway between the vertebræ and sternum: they pierce the External intercostal and Serratus magnus muscles, and divide into two branches, anterior and posterior.

The *anterior branches* are reflected forward to the side and the fore part of the chest, supplying the integument of the chest and mamma and the upper digitations of the External oblique.

The *posterior branches* are reflected backward to supply the integument over the scapula and over the Latissimus dorsi.

The lateral cutaneous branch of the second intercostal nerve is of large size, and does not divide, like the other nerves, into an anterior and posterior branch. It is named, from its origin and distribution, the *intercosto-humeral nerve* (Fig. 461). It pierces the External intercostal muscle, crosses the axilla to the inner side of the arm, and joins with a filament from the nerve of Wrisberg. It then pierces the fascia, and supplies the skin of the upper half of the inner and back part of the arm, communicating with the internal cutaneous branch of the musculo-spiral nerve. The size of this nerve is in inverse proportion to the size of the other cutaneous nerves, especially the nerve of Wrisberg. A second intercosto-humeral nerve is frequently given off from the third intercostal. It supplies filaments to the armpit and inner side of the arm.

The Lower Dorsal Nerves.—The anterior divisions of the seventh, eighth, ninth, tenth, and eleventh dorsal nerves are continued anteriorly from the intercostal spaces into the abdominal wall, and the twelfth dorsal is continued throughout its whole course in the abdominal wall, since it is placed below the last rib; hence these nerves are named *lower* or *abdominal intercostal nerves*. They have (with the exception of the last) the same arrangement as the upper ones as far as the anterior extremities of the intercostal spaces, where they pass behind the costal cartilages, and between the Internal oblique and Transversalis muscles, to the sheath of the Rectus, which they perforate. They supply the Rectus muscle, and terminate in branches which become subcutaneous near the linea alba. These branches are named the anterior cutaneous nerves of the abdomen. They are directed outward as far as the lateral cutaneous nerves, supplying the integument of the front of the belly. The lower intercostal nerves supply the Intercostals, Serratus posticus inferior, and Abdominal muscles, and about the middle of their course give off lateral cutaneous branches, which pierce the External intercostal and External oblique muscles, in the same line as the lateral cutaneous nerves of the thorax, and divide into anterior and posterior branches, which are distributed

to the integument of the abdomen and back, the anterior branches passing nearly as far forward as the margin of the Rectus, the posterior branches passing backward to supply the skin over the Latissimus dorsi, where they join the dorsal cutaneous nerves.

The last dorsal is larger than the other dorsal nerves. Its anterior division runs along the lower border of the last rib in front of the Quadratus lumborum, perforates the Transversalis, and passes forward between it and the Internal oblique to be distributed in the same manner as the lower intercostal nerves. It communicates with the ilio-hypogastric branch of the lumbar plexus, and is frequently connected with the first lumbar nerve by a slender branch, the *dorsi-lumbar nerve*, which descends in the substance of the Quadratus lumborum.

The lateral cutaneous branch of the last dorsal is remarkable for its large size: it perforates the Internal and External oblique muscles, passes downward over the crest of the ilium in front of the iliac branch of the ilio-hypogastric (Fig. 470), and is distributed to the integument of the front of the hip, some of its filaments extending as low down as the trochanter major. It does not divide into an anterior and posterior branch like the other lateral cutaneous branches of the intercostal nerves.

Surgical Anatomy.—The lower seven intercostal nerves and the ilio-hypogastric from the first lumbar nerve supply the skin of the abdominal wall. They run downward and inward fairly equidistant from each other. The sixth and seventh supply the skin over the "pit of the stomach;" the eighth corresponds to about the position of the middle linea transversa; the tenth to the umbilicus; and the ilio-hypogastric supplies the skin over the pubes and external abdominal ring. There are several points of surgical importance about the distribution of these nerves, and it is important to remember their origin and course, for in many diseases affecting the nerve-trunks at or near the origin the pain is referred to their peripheral terminations. Thus in Pott's disease of the spine children will often be brought to the surgeon suffering from pain in the belly. This is due to the fact that the nerves are irritated at the seat of disease as they issue from the spinal canal. When the irritation is confined to a single pair of nerves, the sensation complained of is often a feeling of constriction, as if a cord were tied round the abdomen; and in these cases the situation of the sense of constriction may serve to localize the disease in the spinal column. In other cases, where the bone disease is more extensive and two or more nerves are involved, a more general diffused pain in the abdomen is complained of. A similar condition is sometimes present in affections of the cord itself, as in tabes dorsalis.

Again, it must be borne in mind that the same nerves which supply the skin of the abdomen supply also the planes of muscle which constitute the greater part of the abdominal wall. Hence it follows that any irritation applied to the peripheral terminations of the cutaneous branches in the skin of the abdomen is immediately followed by reflex contraction of the abdominal muscles. A good practical illustration of this may sometimes be seen in watching two surgeons examine the abdomen of the same patient. One, whose hand is cold, causes the muscles of the abdominal wall to at once contract and the belly to become rigid, and thus not nearly so suitable for examination; the other, who has taken the precaution to warm his hand, examines the abdomen without exciting any reflex contraction. The supply of both muscles and skin from the same source is of importance in protecting the abdominal viscera from injury. A blow on the abdomen, even of a severe character, will do no injury to the viscera if the muscles are in a condition of firm contraction; whereas in cases where the muscles have been taken unawares, and the blow has been struck while they were in a state of rest, an injury insufficient to produce any lesion of the abdominal wall has been attended with rupture of some of the abdominal contents. The importance, therefore, of immediate reflex contraction upon the receipt of an injury cannot be overestimated, and the intimate association of the cutaneous and muscular fibres in the same nerve produces a much more immediate response on the part of the muscles to any peripheral stimulation of the cutaneous filaments than would be the case if the two sets of fibres were derived from independent sources.

Again, the nerves supplying the abdominal muscles and skin derived from the lower intercostal nerves are intimately connected with the sympathetic supplying the abdominal viscera through the lower thoracic ganglia from which the splanchnic nerves are derived. In consequence of this, in laceration of the abdominal viscera and in acute peritonitis the muscles of the belly-wall become firmly contracted, and thus as far as possible preserve the abdominal contents in a condition of rest.

THE LUMBAR NERVES.

The lumbar nerves are five in number on each side. The first appears between the first and second lumbar vertebrae, and the last between the last lumbar and the base of the sacrum.

The roots of the lumbar nerves are the largest, and their filaments the most

numerous, of all the spinal nerves, and they are closely aggregated together upon the lower end of the cord. The anterior roots are the smaller, but there is not the same disproportion between them and the posterior roots as in the cervical nerves. The roots of these nerves have a vertical direction, and are of considerable length, more especially the lower ones, since the spinal cord does not extend beyond the first lumbar vertebra. The roots become joined in the intervertebral foramina, and the nerves so formed divide at their exit into two divisions, posterior and anterior.

Posterior Divisions of the Lumbar Nerves.

The posterior divisions of the lumbar nerves (Fig. 463) diminish in size from above downward; they pass backward between the transverse processes, and divide into internal and external branches.

The *internal branches*, the smaller, pass inward close to the articular processes of the vertebrae, and supply the Multifidus spinæ and Interspinales muscles.

The *external branches* supply the Erector spinæ and Intertransverse muscles. From the three upper branches cutaneous nerves are derived which pierce the aponeurosis of the Latissimus dorsi muscle and descend over the back part of the crest of the ilium, to be distributed to the integument of the gluteal region, some of the filaments passing as far as the trochanter major.

Anterior Divisions of the Lumbar Nerves.

The anterior divisions of the lumbar nerves increase in size from above downward. At their origin they communicate with the lumbar ganglia of the sympathetic by long, slender filaments, which accompany the lumbar arteries round the sides of the bodies of the vertebrae, beneath the Psoas muscle. The nerves pass obliquely outward behind the Psoas magnus or between its fasciuli, distributing filaments to it and the Quadratus lumborum. The anterior divisions of the four upper nerves are connected together in this situation by anastomotic loops, and form the *lumbar plexus*. The anterior division of the fifth lumbar, joined with a branch from the fourth, descends across the base of the sacrum to join the anterior division of the first sacral nerve and assist in the formation of the sacral plexus. The cord resulting from the union of the fifth lumbar and the branch from the fourth is called the *lumbo-sacral nerve*.

The Lumbar Plexus.

The *lumbar plexus* is formed by the loops of communication between the anterior divisions of the four upper lumbar nerves. The plexus is narrow above, and often connected with the last dorsal by a slender branch, the *dorsi-lumbar nerve*; it is broad below, where it is joined to the sacral plexus by the lumbo-sacral cord. It is situated in the substance of the Psoas muscle near its posterior part, in front of the transverse processes of the lumbar vertebrae.

The mode in which the plexus is formed is the following: The first lumbar nerve receives a branch from the last dorsal, and gives off a larger branch, which subdivides into the ilio-hypogastric and ilio-inguinal; a communicating branch, which passes down to the second lumbar nerve; and a third branch, which unites with a branch of the second lumbar to form the genito-crural nerve. The second, third, and fourth lumbar nerves divide into an anterior and a posterior division. The anterior division of the second divides into two branches, one of which joins with the above-mentioned branch of the first nerve to form the genito-crural; the other unites with the anterior division of the third nerve and a part of the anterior division of the fourth nerve to form the obturator nerve. The remainder of the anterior division of the fourth nerve passes down to communicate with the fifth lumbar nerve. The posterior divisions of the second and third nerve divide into two branches, a smaller branch from each uniting to form the external

cutaneous nerve, and a larger branch from each, which join with the whole of the posterior division of the fourth lumbar nerve to form the anterior crural. The accessory obturator, when it exists, is formed by a small branch from the third nerve joining with a small branch from the fourth.

From this arrangement it follows that the ilio-hypogastric and ilio-inguinal are derived entirely from the first lumbar nerve; the genito-crural from the first and second nerves; the external cutaneous from the second and third; the anterior crural and obturator by fibres derived from the second, third, and fourth; and the accessory obturator, when it exists, from the third and fourth.

The branches of the lumbar plexus are—the

- Ilio-hypogastric.
- Ilio-inguinal.
- Genito-crural.
- External cutaneous.
- Anterior crural.
- Obturator.
- Accessory obturator.

The **Ilio-hypogastric Nerve** (*superior musculo-cutaneous*) arises from the first lumbar nerve. It emerges from the outer border of the Psoas muscle at its upper part, and crosses obliquely in front of the Quadratus lumborum to the crest of the ilium. It then perforates the Transversalis muscle at its posterior part, near the crest of the ilium, and divides between it and the Internal oblique into two branches, iliac and hypogastric.

The *iliac branch* pierces the Internal and External oblique muscles immediately above the crest of the ilium, and is distributed to the integument of the gluteal region, behind the lateral cutaneous branch of the last dorsal nerve (Fig. 470). The size of this nerve bears an inverse proportion to that of the cutaneous branch of the last dorsal nerve.

The *hypogastric branch* (Fig. 466) continues onward between the Internal oblique and Transversalis muscles. It then pierces the Internal oblique, and near the middle line perforates the aponeurosis of the External oblique, about an inch above and a little to the outer side of the external abdominal ring, and is distributed to the integument of the hypogastric region.

The ilio-hypogastric nerve communicates with the last dorsal and ilio-inguinal nerves.

The **Ilio-inguinal Nerve** (*inferior musculo-cutaneous*), smaller than the preceding, arises with it from the first lumbar nerve. It emerges from the outer border of the Psoas just below the ilio-hypogastric, and, passing obliquely across the Quadratus lumborum and Iliacus muscles, perforates the Transversalis near the fore part of the crest of the ilium, and communicates with the ilio-hypogastric nerve between that muscle and the Internal oblique. The nerve then pierces the Internal oblique, distributing filaments to it; and, accompanying the spermatic cord through the inguinal canal, it escapes at the external abdominal ring, and is

FIG. 464.—Plan of the lumbar plexus.

distributed to the integument of the upper and inner part of the thigh, and to the scrotum in the male and to the labium in the female. The size of this nerve is in inverse proportion to that of the ilio-hypogastric. . Occasionally it is very small, and ends by joining the ilio-hypogastric; in such cases a branch from the ilio-hypogastric takes the place of the ilio-inguinal, or the latter nerve may be altogether absent.

The **Genito-crural Nerve** arises from the first and second lumbar nerves. It passes obliquely through the substance of the Psoas, descends on its surface for some distance, and divides into a genital and crural branch.

The *genital branch* passes outward on the Psoas magnus, and it then pierces

FIG. 465.—The lumbar plexus and its branches.

the fascia transversalis or passes through the internal abdominal ring, descends along the back part of the spermatic cord to the scrotum, and supplies, in the male, the Cremaster muscle. In the female it accompanies the round ligament, and is lost upon it.

The *crural branch* descends on the external iliac artery, sending a few filaments round it, and, passing beneath Poupart's ligament into the thigh, enters the sheath of the femoral vessels, lying superficial and a little external to the femoral artery. It pierces the anterior layer of the sheath of the vessels, and, becoming superficial by passing through the fascia lata, it supplies the skin of the anterior aspect of the thigh as far as midway between the pelvis and knee. On the front of the thigh it communicates with the outer branch of the middle cutaneous nerve, derived from the anterior crural.

FIG. 466.—Cutaneous nerves of lower extremity. Front view.

FIG. 467.—Nerves of the lower extremity. Front view.

A few filaments from this nerve may be traced on to the femoral artery; they are derived from the nerve as it passes beneath Poupart's ligament.

The **External Cutaneous Nerve** arises from the second and third lumbar nerves. It emerges from the outer border of the Psoas muscle about its middle, and crosses the Iliacus muscle obliquely, to the notch immediately beneath the anterior superior spine of the ilium, where it passes under Poupart's ligament into the thigh, and divides into two branches, anterior and posterior.

The *anterior branch* descends in an aponeurotic canal formed in the fascia lata, becomes superficial about four inches below Poupart's ligament, and divides into branches which are distributed to the integument along the anterior and outer part of the thigh, as far down as the knee. This nerve occasionally communicates with a branch of the long saphenous nerve in front of the knee-joint.

The *posterior branch* pierces the fascia lata, and subdivides into branches which pass backward across the outer and posterior surface of the thigh, supplying the integument from the crest of the ilium as far as the middle of the thigh.

The **Obturator Nerve** supplies the obturator externus and Adductor muscles of the thigh, the articulations of the hip and knee, and occasionally the integument of the thigh and leg. It arises by three branches—from the third, the fourth, and the fifth lumbar nerves. It descends through the inner fibres of the Psoas muscle, and emerges from its inner border near the brim of the pelvis; it then runs along the lateral wall of the pelvis, above the obturator vessels, to the upper part of the obturator foramen, where it enters the thigh, and divides into an anterior and a posterior branch, separated by some of the fibres of the Obturator externus, and lower down by the Adductor brevis muscle.

The *anterior branch* (Fig. 467) passes down in front of the Adductor brevis, being covered by the Pectineus and Adductor longus, and at the lower border of the latter muscle communicates with the internal cutaneous and internal saphenous nerves, forming a kind of plexus. It then descends upon the femoral artery, upon which it is finally distributed. The nerve, near the obturator foramen, gives off an articular branch to the hip-joint. Behind the Pectineus it distributes muscular branches to the Adductor longus and Gracilis, and occasionally to the Adductor brevis and Pectineus, and receives a communicating branch from the accessory obturator nerve.

Occasionally the communicating branch to the internal cutaneous and internal saphenous nerves is continued down, as a cutaneous branch, to the thigh and leg. When this is so, this occasional cutaneous branch emerges from beneath the lower border of the Adductor longus, descends along the posterior margin of the Sartorius to the inner side of the knee, where it pierces the deep fascia, communicates with the long saphenous nerve, and is distributed to the integument of the inner side of the leg as low down as its middle. When this communicating branch is small, its place is supplied by the internal cutaneous nerve.

The *posterior branch of the obturator nerve* pierces the Obturator externus, sending branches to supply it, and passes behind the Adductor brevis on the front of the Adductor magnus, where it divides into numerous muscular branches, which supply the Adductor magnus, and occasionally the Adductor brevis. One of the branches gives off a filament to the knee-joint.

The *articular branch for the knee-joint* perforates the lower part of the Adductor magnus and enters the popliteal space; it then descends upon the popliteal artery as far as the back part of the knee-joint, where it perforates the posterior ligament, and is distributed to the synovial membrane. It gives filaments to the artery in its course.

The **Accessory Obturator Nerve** (Fig. 465) is not constantly present. It is of small size, and arises by separate filaments from the third and fourth lumbar nerves. It descends along the inner border of the Psoas muscle, crosses the horizontal ramus of the os pubis, and passes under the outer border of the Pectineus muscle, where it divides into numerous branches. One of these supplies the Pectineus, penetrating its under surface; another is distributed to the hip-joint; while a third communicates with the anterior branch of the obturator nerve. When this nerve

is absent the hip-joint receives two branches from the obturator nerve. Occasionally it is very small, and becomes lost in the capsule of the hip-joint.

The **Anterior Crural Nerve** (Figs. 465, 467) is the largest branch of the lumbar plexus. It supplies muscular branches to the Iliacus, Pectineus, and all the muscles on the front of the thigh, excepting the Tensor vaginae femoris; cutaneous filaments to the front and inner side of the thigh and to the leg and foot; and articular branches to the hip and knee. It arises from the second, third, and fourth lumbar nerves. It descends through the fibres of the Psoas muscle, emerging from it at the lower part of its outer border, and passes down between it and the Iliacus, and beneath Poupart's ligament, into the thigh, where it becomes somewhat flattened, and divides into an anterior part which passes superficial to the external circumflex vessels, and a posterior part which passes beneath these vessels. Under Poupart's ligament it is separated from the femoral artery by the Psoas muscle, and lies beneath the iliac fascia.

Within the pelvis the anterior crural nerve gives off from its outer side some small branches to the Iliacus, and a branch to the femoral artery which is distributed upon the upper part of that vessel. The origin of this branch varies: it occasionally arises higher than usual, or it may arise lower down in the thigh.

External to the pelvis the following branches are given off:

From the Anterior Division.

Middle cutaneous.
Internal cutaneous.

From the Posterior Division.

Long saphenous.
Muscular.
Articular.

The *middle cutaneous nerve* (Fig. 466) pierces the fascia lata (generally the Sartorius also) about three inches below Poupart's ligament, and divides into two branches, which descend in immediate proximity along the fore part of the thigh, distributing numerous branches to the integument as low as the front of the knee, where it communicates with the *nervus cutaneus patellæ*, a branch of the internal saphenous nerve, helping to form the patellar plexus. Its outer branch communicates, above, with the crural branch of the genito-crural nerve, and the inner branch with the internal cutaneous nerve below. The Sartorius muscle is supplied by this or the following nerve.

The *internal cutaneous nerve* passes obliquely across the upper part of the sheath of the femoral artery, and divides in front or at the inner side of that vessel into two branches, anterior and posterior or internal.

The *anterior branch* runs downward on the Sartorius, perforates the fascia lata at the lower third of the thigh, and divides into two branches, one of which supplies the integument as low down as the inner side of the knee; the other crosses to the outer side of the patella, communicating in its course with the *nervus cutaneus patellæ*, a branch of the internal saphenous nerve.

The *posterior or internal branch* descends along the inner border of the Sartorius muscle to the knee, where it pierces the fascia lata, communicates with the long saphenous nerve, and gives off several cutaneous branches. The nerve then passes down the inner side of the leg, to the integument of which it is distributed. This nerve, beneath the fascia lata, at the lower border of the Adductor longus, joins in a plexiform network by uniting with branches of the long saphenous and obturator nerves (Fig. 467). When the communicating branch from the obturator nerve is large and continued to the integument of the leg, the inner branch of the internal cutaneous is small and terminates at the plexus, occasionally giving off a few cutaneous filaments.

The internal cutaneous nerve, before dividing, gives off a few filaments, which pierce the fascia lata, to supply the integument of the inner side of the thigh, accompanying the long saphenous vein. One of these filaments passes through the saphenous opening; a second becomes subcutaneous about the middle of the thigh; and a third pierces the fascia at its lower third.

The *long or internal saphenous nerve* is the largest of the cutaneous branches of the anterior crural. It approaches the femoral artery where this vessel passes beneath the Sartorius, and lies on its outer side, beneath the aponeurotic covering of Hunter's canal, as far as the opening in the lower part of the Adductor magnus. It then quits the artery, and descends vertically along the inner side of the knee, beneath the Sartorius, pierces the fascia lata, opposite the interval between the tendons of the Sartorius and Gracilis, and becomes subcutaneous. The nerve then passes along the inner side of the leg, accompanied by the internal saphenous vein, descends behind the internal border of the tibia, and, at the lower third of the leg, divides into two branches: one continues its course along the margin of the tibia, terminating at the inner ankle; the other passes in front of the ankle, and is distributed to the integument along the inner side of the foot, as far as the great toe, communicating with the internal branch of the musculo-cutaneous nerve.

Branches.—The long saphenous nerve *about the middle of the thigh* gives off a communicating branch which joins the plexus formed by the obturator and internal cutaneous nerves.

At the inner side of the knee it gives off a large branch (*nervus cutaneus patellæ*) which pierces the Sartorius and fascia lata, and is distributed to the integument in front of the patella. This nerve communicates above the knee with the anterior branch of the internal cutaneous and with the middle cutaneous; below the knee, with other branches of the long saphenous; and on the outer side of the joint, with branches of the external cutaneous nerve, forming a plexiform network, the *plexus patellæ*. The cutaneous nerve of the patella is occasionally small, and terminates by joining the internal cutaneous, which supplies its place in front of the knee.

Below the knee the branches of the long saphenous nerve are distributed to the integument of the front and inner side of the leg, communicating with the cutaneous branches from the internal cutaneous or from the obturator nerve.

The *muscular branches* supply the Pectineus and all the muscles on the front of the thigh, except the Tensor vaginae femoris, which is supplied from the superior gluteal nerve, and the Sartorius, which is supplied by filaments from the middle or internal cutaneous nerves.

The *branches to the Pectineus*, usually two in number, pass inward behind the femoral vessels, and enter the muscle on its anterior surface. Sometimes one of these nerves is given off in the pelvis, and is then often united with the accessory obturator.

The *branch to the Rectus muscle* enters its under surface high up, sending off a small filament to the hip-joint.

The *branch to the Vastus externus*, of large size, follows the course of the descending branch of the external circumflex artery to the lower part of the muscle. It gives off an articular filament to the knee-joint.

The *branch to the Vastus internus* is a long branch which runs down on the outer side of the femoral vessels in company with the internal saphenous nerve for its upper part. It enters the muscle about its middle, and gives off a filament which can usually be traced downward on the surface of the muscle to the knee-joint.

The *branch to the Crureus* enters the muscle on its anterior surface about the middle of the thigh, and sends a filament through the muscle to the Sub-crureus.

The *articular branch to the hip-joint* is derived from the nerve to the Rectus.

The *articular branches to the knee-joint* are two in number. One, a long, slender filament, is derived from the nerve to the Vastus externus. It penetrates the capsular ligament of the joint on its anterior aspect. The other is derived from the nerve to the Vastus internus. It can usually be traced downward on the surface of this muscle to near the joint; it then penetrates the muscular fibres,

and accompanies the deep branch of the anastomotica magna artery, pierces the capsular ligament of the joint on its inner side, and supplies the synovial membrane.

THE SACRAL AND COCCYGEAL NERVES.

The *sacral nerves* are five in number on each side. The four upper ones pass from the sacral canal through the sacral foramina; the fifth through the foramen between the sacrum and coccyx.

The *roots of origin of the upper sacral (and lumbar) nerves* are the largest of all the spinal nerves, whilst those of the lowest sacral and coccygeal nerve are the smallest.

The *roots* of these nerves are of very considerable length, being longer than those of any of the other spinal nerves, on account of the spinal cord not extending beyond the first lumbar vertebra. From their great length and the appearance they present in connection with the spinal cord the roots of origin of these nerves are called collectively the *cauda equina*. Each sacral and coccygeal nerve divides into two divisions, posterior and anterior.

The *posterior divisions of the sacral nerve* (Fig. 468) are small, diminish in

FIG. 468.—The posterior sacral nerves.

size from above downward, and emerge, except the last, from the sacral canal by the posterior sacral foramina.

The *three upper ones* are covered, at their exit from the sacral canal, by the Multifidus spinæ, and divide into internal and external branches.

The *internal branches* are small, and supply the Multifidus spinæ.

The *external branches* join with one another and with the last lumbar and fourth sacral nerves by means of communicating loops. These branches pass outward to the outer surface of the great sacro-sciatic ligament, where they form a second series of loops beneath the Gluteus maximus. Cutaneous branches from this second series of loops, usually three in number, pierce the Gluteus maximus:

one near the posterior inferior spine of the ilium; another opposite the end of the sacrum; and the third midway between the other two. They supply the integument over the posterior part of the gluteal region.

The *posterior divisions of the two lower sacral nerves* are situated below the Multifidus spinæ. They are of small size, and do not divide into internal and external branches, but join with each other, and with the coccygeal nerve, so as to form loops on the back of the sacrum, filaments from which supply the Extensor coccygis and the integument over the coccyx.

The **coccygeal nerve** divides into its anterior and posterior divisions in the spinal canal. The *posterior division* is the smaller. It does not divide, but receives, as already mentioned, a communicating branch from the last sacral, and is lost in the fibrous structure on the back of the coccyx.

The *anterior divisions of the sacral nerves* diminish in size from above down-

FIG. 469.—Side view of pelvis, showing sacral nerves.

ward. The four upper ones emerge from the anterior sacral foramina: the anterior division of the fifth, after emerging from the spinal canal through its terminal opening, curves forward between the sacrum and the coccyx. All the anterior sacral nerves communicate with the sacral ganglia of the sympathetic at their exit from the sacral foramina. The *first nerve*, of large size, unites with the lumbo-sacral cord, formed by the fifth lumbar, and a branch from the fourth. The *second*, equal in size to the preceding, and the *third*, about one-fourth the size of the second, unite with this trunk, and form, with a small fasciculus from the fourth, the *sacral plexus*, a visceral branch being given off from the third nerve to the bladder.

The **fourth anterior sacral nerve** sends a branch to join the sacral plexus. The remaining portion of the nerve divides into visceral and muscular branches, and a communicating filament descends to join the fifth sacral nerve. The *visceral branches* are distributed to the viscera of the pelvis, communicating with the

sympathetic nerve. These branches ascend upon the rectum and bladder, and in the female upon the vagina, communicating with branches of the sympathetic from the pelvic plexus. The *muscular branches* are distributed to the Levator ani, Coccygeus, and Sphincter ani. The branch to the Sphincter ani pierces the Levator ani, so as to reach the ischio-rectal fossa, where it is found lying in front of the coccyx. Cutaneous filaments arise from the latter branch, which supply the integument between the anus and coccyx. Another cutaneous branch is frequently given off from this nerve, though sometimes from the pudic (Schwalbe). It perforates the great sacro-sciatic ligament, and, winding round the lower border of the Gluteus maximus, supplies the skin over the lower and inner part of this muscle.

The **fifth anterior sacral nerve**, after passing from the lower end of the sacral canal, curves forward through the fifth sacral foramen, formed between the lower part of the sacrum and the transverse process of the first piece of the coccyx. It pierces the Coccygeus muscle, and descends upon its anterior surface to near the tip of the coccyx, where it again perforates the muscle, to be distributed to the integument over the back part and side of the coccyx. This nerve communicates above with the fourth sacral and below with the coccygeal nerve, and supplies the Coccygeus muscle.

The **anterior division of the coccygeal nerve** is a delicate filament which escapes at the termination of the sacral canal; it passes downward behind the rudimentary transverse process of the first piece of the coccyx, and curves forward through the notch between the first and second pieces, piercing the Coccygeus muscle, and descending on its anterior surface to near the tip of the coccyx, where it again pierces the muscle, to be distributed to the integument over the back part and side of the coccyx. It is joined by a branch from the fifth anterior sacral as it descends on the surface of the Coccygeus muscle.

The Sacral Plexus (Fig. 469).

The **sacral plexus** is formed by the lumbo-sacral cord, the anterior divisions of the three upper sacral nerves, and part of that of the fourth. These nerves proceed in different directions; the upper ones obliquely downward and outward, the lower one nearly horizontally, and they all unite into a single, broad, flat cord. The sacral plexus is triangular in form, its base corresponding with the exit of the nerves from the sacrum, its apex with the lower part of the great sacro-sciatic foramen. It rests upon the anterior surface of the Piriformis, and is covered in front by the pelvic fascia, which separates it from the sciatic and pudic branches of the internal iliac artery and from the viscera of the pelvis.

The branches of the sacral plexus are—

Muscular.	Pudic.
Superior gluteal.	Small sciatic.
Inferior gluteal.	Great sciatic.

The **muscular branches** supply the Piriformis, Obturator internus, the two Gemelli, and the Quadratus femoris. The branch to the Piriformis arises either from the plexus or from the upper sacral nerves before they enter the plexus; the branch to the Obturator internus arises at the junction of the lumbo-sacral and first sacral nerves: it passes out of the pelvis through the great sacro-sciatic foramen, crosses the spine of the ischium, and re-enters the pelvis through the lesser sacro-sciatic foramen to the inner surface of the Obturator internus; the branch to the Gemellus superior arises in common with the nerve to the Obturator internus: it enters the muscle at the upper part of its posterior surface; the small branch to the Gemellus inferior and Quadratus femoris also arises from the upper part of the plexus: it passes through the great sacro-sciatic foramen, and courses down beneath the Gemelli and tendon of the Obturator internus, and supplies the muscles on their deep or anterior surface. It gives off an articular

FIG. 470.—Cutaneous nerves of lower extremity. Posterior view.

FIG. 471.—Nerves of the lower extremity¹. Posterior view.

¹ N. B.—In this diagram the external saphenous and communicans peronei are not in their normal position. They have been displaced by the removal of the superficial muscles.

branch to the hip-joint. This articular branch is occasionally derived from the upper part of the great sciatic nerve.

The **Superior Gluteal Nerve** (Fig. 471) arises from the back part of the lumbo-sacral cord, with some filaments from the first sacral nerve: it passes from the pelvis through the great sacro-sciatic foramen above the Piriformis muscle, accompanied by the gluteal vessels, and divides into a superior and an inferior branch.

The *superior branch* follows the line of origin of the Gluteus minimus, and supplies the Gluteus medius.

The *inferior branch* crosses obliquely between the Gluteus minimus and medius, distributing filaments to both these muscles, and terminates in the Tensor vaginæ femoris, extending nearly to its lower end.

The **Inferior Gluteal** arises from the lumbo-sacral cord and first and second sacral nerves, and is intimately connected with the small sciatic at its origin. It passes out of the pelvis through the great sciatic notch, beneath the Piriformis muscle, and, dividing into a number of branches, enters the Gluteus maximus muscle on its under surface. It gives off a cutaneous branch, which winds round the lower border of the Gluteus maximus muscle to supply the skin of the buttock. It is said also to give an articular branch to the hip-joint.

The **Pudic Nerve** arises from the lower part of the sacral plexus, and leaves the pelvis, through the great sacro-sciatic foramen, below the Piriformis. It then crosses the spine of the ischium, and re-enters the pelvis through the lesser sacro-sciatic foramen. It accompanies the pudic vessels upward and forward along the outer wall of the ischio-rectal fossa, being contained in a sheath of the Obturator fascia, and divides into two terminal branches, the perineal nerve and the dorsal nerve of the penis. Before its division it gives off the inferior hæmorrhoidal nerve.

The *inferior hæmorrhoidal nerve* is occasionally derived separately from the sacral plexus. It passes across the ischio-rectal fossa, with its accompanying vessels, toward the lower end of the rectum, and is distributed to the integument round the anus. Branches of this nerve communicate with the inferior pudendal and superficial perineal nerves at the fore part of the perinæum.

The *perineal nerve*, the inferior and larger of the two terminal branches of the pudic, is situated below the pudic artery. It accompanies the superficial perineal artery in the perinæum, dividing into cutaneous and muscular branches.

The cutaneous branches (superficial perineal) are two in number, posterior and anterior. The *posterior or external branch* passes forward along the outer side of the perineal space parallel to the inferior pudendal nerve, and is distributed to the skin of the scrotum. It communicates with the inferior hæmorrhoidal, the inferior pudendal, and the other superficial perineal nerve. The *anterior or internal branch* passes forward nearer to the middle line, to be distributed to the inner and back part of the scrotum. Both these nerves supply the labia majora in the female.

The muscular branches are distributed to the Transversus perinæi, Accelerator urinæ, Erector penis, and Compressor urethræ. A distinct branch is given off from the nerve to the Accelerator urinæ, which pierces this muscle and supplies the corpus spongiosum, ending in the mucous membrane of the urethra. This is the nerve to the bulb.

The *dorsal nerve of the penis* is the deepest division of the pudic nerve; it accompanies the pudic artery along the ramus of the ischium: piercing the posterior layer of the deep perineal fascia, it runs forward along the inner margin of the ramus of the os pubis, between the two layers of the deep fascia. It then pierces the anterior layer, and, in company with the dorsal artery of the penis, passes through the suspensory ligament, and, running forward, is distributed to the glans. On the penis this nerve gives off a cutaneous branch which runs along the side of the organ; it is joined with branches of the sympathetic, and supplies the integument of the upper surface and sides of the penis and prepuce, giving a large branch to the corpus cavernosum.

In the female the dorsal nerve is very small and supplies the clitoris.

The **Small Sciatic Nerve** (Fig. 471) supplies the integument of the perinæum and back part of the thigh and leg. It is usually formed by the union of two branches, which arise from the second and third nerves of the sacral plexus. It issues from the pelvis through the great sacro-sciatic foramen below the Piriformis muscle, descends beneath the Gluteus maximus with the sciatic artery, and at the lower border of that muscle passes along the back part of the thigh, beneath the fascia lata, to the lower part of the popliteal region, where it pierces the fascia and becomes cutaneous. It then accompanies the external saphenous vein to about the middle of the leg, its terminal filaments communicating with the external saphenous nerve.

The branches of the small sciatic nerve are all cutaneous, and consist of four groups—internal, external, ascending, and descending.

The *internal cutaneous branches* are distributed to the skin at the upper and inner side of the thigh, on its posterior aspect. One branch, longer than the rest, the *inferior pudendal*, curves forward below the tuber ischii, pierces the fascia lata, and passes forward beneath the superficial fascia of the perinæum to be distributed to the integument of the scrotum in the male and the labium in the female, communicating with the superficial perineal and inferior hæmorrhoidal nerves.

The *external cutaneous branches* consist of two or three filaments, which are distributed to the skin at the upper and outer side of the thigh on its posterior aspect, as far down as the middle of that region.

The *ascending cutaneous branches* consist of two or three filaments, which turn upward round the lower border of the gluteus maximus, to supply the integument covering its surface.

The *descending cutaneous branches* are given off from the lesser sciatic nerve as it descends beneath the fascia of the thigh; they supply the integument of the back part of the thigh, popliteal region, and upper part of the leg.

The **Great Sciatic Nerve** (Fig. 471) supplies nearly the whole of the integument of the leg, the muscles of the back of the thigh, and those of the leg and foot. It is the largest nervous cord in the body, measuring three-quarters of an inch in breadth, and is the continuation of the lower part of the sacral plexus. It passes out of the pelvis through the great sacro-sciatic foramen, below the Piriformis muscle. It descends between the trochanter major and tuberosity of the ischium, along the back part of the thigh to about its lower third, where it divides into two large branches, the *internal* and *external popliteal nerves*.

This division may take place at any point between the sacral plexus and the lower third of the thigh. When the division occurs at the plexus, the two nerves descend together, side by side; or they may be separated at their commencement by the interposition of part or the whole of the Piriformis muscle. As the nerve descends along the back of the thigh it rests at first upon the External rotator muscles, in company with the small sciatic nerve and artery, being covered by the Gluteus maximus; lower down, it lies upon the Adductor magnus and is covered by the long head of the Biceps.

The *branches* of the nerve, before its division, are articular and muscular.

The *articular branches* arise from the upper part of the nerve; they supply the hip-joint, perforating its fibrous capsule posteriorly. These branches are sometimes derived from the sacral plexus.

The *muscular branches* are distributed to the Flexors of the leg—viz. the Biceps, Semitendinosus, and Semimembranosus, and a branch to the Adductor magnus. These branches are given off beneath the Biceps muscle.

The **Internal Popliteal Nerve**, the larger of the two terminal branches of the great sciatic, descends along the back part of the thigh, through the middle of the popliteal space, to the lower part of the Popliteus muscle, where it passes with the artery beneath the arch of the Soleus and becomes the posterior tibial. It is overlapped by the hamstring muscles above, and then becomes more super-

ficial, and lies to the outer side of, and some distance from, the popliteal vessels; opposite the knee-joint it is in close relation with the vessels, and crosses to the inner side of the artery. Below, it is overlapped by the Gastrocnemius.

The *branches* of this nerve are—articular, muscular, and a cutaneous branch, the *communicans poplitei* nerve.

The *articular branches*, usually three in number, supply the knee-joint: two of these branches accompany the superior and inferior internal articular arteries, and a third, the azygos articular artery.

The *muscular branches*, four or five in number, arise from the nerve as it lies between the two heads of the Gastrocnemius muscle; they supply that muscle, the Plantaris, Soleus, and Popliteus. The filaments which supply the Popliteus turn round its lower border and are distributed to its deep surface.

The *communicans poplitei* descends between the two heads of the Gastrocnemius muscle, and about the middle of the back of the leg pierces the deep fascia, and joins a communicating branch (*communicans peronei*) from the external popliteal nerve to form the external or short saphenous (Fig. 470). The external saphenous nerve, formed by the cutaneous branches of the internal and external popliteal nerves, passes downward and outward near the outer margin of the tendo Achillis, lying close to the external saphenous vein, to the interval between the external malleolus and the os calcis. It winds round the outer malleolus, and is distributed to the integument along the outer side of the foot and little toe, communicating on the dorsum of the foot with the musculo-cutaneous nerve. In the leg its branches communicate with those of the small sciatic.

The **Posterior Tibial Nerve** (Fig. 471) commences at the lower border of the Popliteus muscle, and passes along the back part of the leg with the posterior tibial vessels to the interval between the inner malleolus and the heel, where it divides into the *external* and *internal plantar nerves*. It lies upon the deep muscles of the leg, and is covered in the upper part by the muscles of the calf, lower down by the skin and fascia. In the upper part of its course it lies to the inner side of the posterior tibial artery, but it soon crosses that vessel, and lies to its outer side as far as the ankle. In the lower third of the leg it is placed parallel with the inner margin of the tendo Achillis.

The *branches of the posterior tibial nerve* are—muscular, plantar cutaneous, and articular.

The *muscular branches* arise either separately or by a common trunk from the upper part of the nerve. They supply the Tibialis posticus, Flexor longus digitorum, and Flexor longus hallucis muscles, the branch to the latter muscle accompanying the peroneal artery.

The *plantar cutaneous branch* perforates the internal annular ligament and supplies the integument of the heel and inner side of the sole of the foot.

The *articular branch* is given off just above the bifurcation of the nerve and supplies the ankle-joint.

The **internal plantar nerve** (Fig. 472), the larger of the two terminal branches of the posterior tibial, accompanies the internal plantar artery along the inner side of the foot. From its origin at the inner ankle it passes beneath the Abductor hallucis, and then forward between this muscle and the Flexor brevis digitorum, divides opposite the bases of the metatarsal bones into four digital branches, and communicates with the external plantar nerve.

Branches.—In its course the internal plantar nerve gives off *cutaneous branches*, which pierce the plantar fascia and supply the integument of the sole of the foot; *muscular branches*, which supply the Abductor hallucis and Flexor brevis digitorum; *articular branches*, to the articulations of the tarsus and metatarsus; and *four digital branches*. These pass between the divisions of the plantar fascia in the clefts between the toes, and are distributed in the following manner: The *first* supplies the inner border of the great toe, and sends a filament to the Flexor brevis hallucis muscle; the *second* bifurcates to supply the adjacent sides of the great and second toes, sending a filament

to the First lumbrical muscle; the *third digital branch* supplies the adjacent sides of the second and third toes, and the Second lumbrical muscle; the

fourth supplies the corresponding sides of the third and fourth toes, and receives a communicating branch from the external plantar nerve. It will be observed that the distribution of these branches is precisely similar to that of the median nerve in the hand. Each digital nerve gives off cutaneous and articular filaments, and opposite the last phalanx sends a dorsal branch, which supplies the structure round the nail, the continuation of the nerve being distributed to the ball of the toe.

The **external plantar nerve**, the smaller of the two, completes the nervous supply to the structures of the sole of the foot, being distributed to the little toe and one-half of the fourth, as well as to most of the deep muscles, its distribution being similar to that of the ulnar in the hand. It passes obliquely forward with the external plantar artery to the outer side of the foot, lying between the Flexor brevis digitorum and Flexor accessorius, and in the interval between the former muscle and Abductor minimi digiti divides into a superficial and a deep branch. Before its division it supplies the Flexor accessorius and Abductor minimi digiti.

The *superficial branch* separates into two digital nerves: one, the smaller of

the two, supplies the outer side of the little toe, the Flexor brevis minimi digiti, and the two Interosseous muscles of the fourth metatarsal space; the other and larger digital branch supplies the adjoining sides of the fourth and fifth toes, and communicates with the internal plantar nerve.

The *deep or muscular branch* accompanies the external plantar artery into the deep part of the sole of the foot, beneath the tendons of the Flexor muscles and Adductor transversus hallucis, and supplies all the Interossei (except those in the fourth metatarsal space), the two outer Lumbricales, the Adductor obliquus hallucis, and the Adductor transversus hallucis.

The **External Popliteal or Peroneal Nerve** (Fig. 471), about one-half the size of the internal popliteal, descends obliquely along the outer sides of the popliteal space to the head of the fibula, close to the inner margin of the Biceps muscle. It is easily felt beneath the skin behind the head of the fibula at the inner side of the tendon of the Biceps. It passes between the tendon of the Biceps and outer head of the Gastrocnemius muscle, winds round the neck of the fibula, pierces the origin of the Peroneus longus, and divides beneath that muscle into the anterior tibial and musculo-cutaneous nerves.

The *branches of the peroneal nerve*, previous to its division, are articular and cutaneous.

The *articular branches* are three in number; two of these accompany the superior and inferior external articular arteries to the outer side of the knee. The upper one occasionally arises from the great sciatic nerve before its bifurcation. The third (*recurrent*) articular nerve is given off at the point of division of the peroneal nerve; it ascends with the anterior recurrent tibial artery through the Tibialis anticus muscle to the front of the knee, which it supplies.

FIG. 472.—The plantar nerves.

The *cutaneous branches*, two or three in number, supply the integument along the back part and outer side of the leg as far as its middle or lower part; one of these, larger than the rest, the *communicans peronei*, arises near the head of the fibula, crosses the external head of the Gastrocnemius to the middle of the leg, and joins with the *communicans poplitei* to form the external saphenous. This nerve occasionally exists as a separate branch, which is continued down as far as the heel.

The **Anterior Tibial Nerve** (Fig. 467) commences at the bifurcation of the peroneal nerve, between the fibula and upper part of the Peroneus longus, passes obliquely forward beneath the Extensor longus digitorum to the fore part of the interosseous membrane, and reaches the outer side of the anterior tibial artery above the middle of the leg; it then descends with the artery to the front of the ankle-joint, where it divides into an external and an internal branch. This nerve lies at first on the outer side of the anterior tibial artery, then in front of it, and again at its outer side at the ankle-joint.

The *branches of the anterior tibial nerve* in its course through the leg are the muscular branches to the Tibialis anticus, Extensor longus digitorum, Peroneus tertius, and Extensor proprius hallucis muscles, and an *articular branch* to the ankle-joint.

The *external or tarsal branch of the anterior tibial* passes outward across the tarsus, beneath the Extensor brevis digitorum, and, having become ganglionic, like the posterior interosseous nerve at the wrist, supplies the Extensor brevis digitorum. From the ganglion are given off three minute *interosseous branches* which supply the tarsal joints and the metatarso-phalangeal joints of the second, third, and fourth toes. The first of these sends a filament to the second dorsal interosseous muscle.

The *internal branch*, the continuation of the nerve, accompanies the dorsalis pedis artery along the inner side of the dorsum of the foot, and at the first interosseous space divides into two branches, which supply the adjacent sides of the great and second toes, communicating with the internal branch of the musculo-cutaneous nerve. Before it divides it gives off an *interosseous branch* to the first space, which supplies the metatarso-phalangeal joint of the great toe and sends a filament to the First dorsal interosseous muscle.

The **Musculo-cutaneous Nerve** (Fig. 467) supplies the muscles on the fibular side of the leg and the integument of the dorsum of the foot. It passes forward between the Peronei muscles and the Extensor longus digitorum, pierces the deep fascia at the lower third of the leg on its front and outer side, and divides into two branches. This nerve in its course between the muscles gives off muscular branches to the Peroneus longus and brevis, and cutaneous filaments to the integument of the lower part of the leg.

The *internal branch of the musculo-cutaneous nerve* passes in front of the ankle-joint and along the dorsum of the foot, supplying the inner side of the great toe and the adjoining sides of the second and third toes. It also supplies the integument of the inner ankle and inner side of the foot, communicating with the internal saphenous nerve, and joins with the anterior tibial nerve between the great and second toes.

The *external branch*, the larger, passes along the outer side of the dorsum of the foot, to be distributed to the adjoining sides of the third, fourth, and fifth toes. It also supplies the integument of the outer ankle and outer side of the foot, communicating with the short saphenous nerve.

The distribution of these branches of the musculo-cutaneous nerve will be found to vary; together, they supply all the toes excepting the outer side of the little toe and the adjoining sides of the great and second toes, the former being supplied by the external saphenous, and the latter by the internal branch of the anterior tibial.

Surgical Anatomy.—The lumbar plexus passes through the Psoas muscle, and, therefore in psoas abscess any or all of its branches may be irritated, causing severe pain in the part to

which the irritated nerves are distributed. The genito-crural nerve is the one which is most frequently implicated. This nerve is also of importance, as it is concerned in one of the principal reflexes employed in the investigation of diseases of the spine. If the skin over the inner side of the thigh just below Poupart's ligament, the part supplied by the crural branch of the genito-crural nerve, be gently tickled in a male child, the testicle will be noticed to be drawn upward through the action of the Cremaster muscle, supplied by the genital branch of the same nerve. The same result may sometimes be noticed in adults, and can almost always be produced by severe stimulation. This reflex, when present, shows that the portion of the cord from which the first and second lumbar nerves are derived is in a normal condition.

The anterior crural nerve is in danger of being injured in fractures of the true pelvis, since the fracture most commonly takes place through the horizontal ramus of the os pubis, at or near the point where this nerve crosses the bone. It is also liable to be injured in fractures and dislocations of the femur, and is likely to be pressed upon and its functions impaired in some tumors growing in the pelvis. Moreover, on account of its superficial position it is exposed to injury in wounds and stabs in the groin. When this nerve is paralyzed, the patient is unable to flex his hip completely, on account of the loss of motion in the Iliacus, or to extend the knee on the thigh, on account of paralysis of the Quadriceps extensor cruris; there is complete paralysis of the Sartorius and partial paralysis of the Pectineus. There is loss of sensation down the front and inner side of the thigh, except in that part supplied by the crural branch of the genito-crural and by the ilio-inguinal. There is also loss of sensation down the inner side of the leg and foot as far as the ball of the great toe.

The obturator nerve is of special surgical interest. It is rarely paralyzed alone, but occasionally in association with the anterior crural. The principal interest attached to it is in connection with its supply to the knee, pain in the knee being symptomatic of many diseases in which the trunk of this nerve or one of its branches is irritated. Thus it is well known that in the earlier stages of hip-joint disease the patient does not complain of pain in that articulation, but on the inner side of the knee, or in the knee-joint itself, both these articulations being supplied by the obturator nerve, the final distribution of the nerve being to the knee-joint. Again, the same thing occurs in sacro-iliac disease: pain is complained of in the knee-joint or on its inner side. The obturator nerve is in close relationship with the sacro-iliac articulation, passing over it, and, according to some anatomists, distributing filaments to it. Again, in cancer of the sigmoid flexure, and even in cases where masses of hardened feces are impacted in this portion of the gut, pain is complained of in the knee. The obturator nerve lies beneath the sigmoid flexure, and is readily pressed upon and irritated when disease exists in this part of the intestine. Finally, pain in the knee forms an important diagnostic sign in obturator hernia. The hernial protrusion as it passes out through the opening in the obturator membrane presses upon the nerve and causes pain in the parts supplied by its peripheral filaments. When the obturator nerve is paralyzed, the patient is unable to press his knees together or to cross one leg over the other, on account of paralysis of the Adductor muscles. Rotation outward of the thigh is impaired from paralysis of the Obturator externus. Sometimes there is loss of sensation in the upper half of the inner side of the leg.

The great sciatic nerve is liable to be pressed upon by various forms of pelvic tumors, giving rise to pain along its trunk, to which the term sciatica is applied. Tumors growing from the pelvic viscera or bones, aneurisms of some of the branches of the internal iliac artery, calculus in the bladder when of large size, accumulation of feces in the rectum, may all cause pressure on the nerve inside the pelvis and give rise to sciatica. Outside the pelvis exposure to cold, violent movements of the hip-joint, exostoses or other tumors growing from the margin of the sacro-sciatic foramen, may also give rise to the same condition. When paralyzed there is loss of motion in all the muscles below the knee, and loss of sensation in the same situation, except the upper half of the back of the leg, supplied by the small sciatic and the upper half of the inner side of the leg, when the communicating branch of the obturator is large (see page 816).

The sciatic nerve has been frequently cut down upon and stretched, or has been acupunctured for the relief of sciatica. The nerve has also been stretched in cases of locomotor ataxy, the anaesthesia of leprosy, etc. In order to define it on the surface, a point is taken at the junction of the middle and lower third of a line stretching from the posterior superior spine of the ilium to the outer part of the tuber ischii, and a line drawn from this to the middle of the upper part of the popliteal space. The line must be slightly curved with its convexity outward, and as it passes downward to the lower border of the Gluteus maximus is slightly nearer the tuber ischii than the great trochanter, as it bisects a line drawn between these two points. The operation of stretching the sciatic nerve is performed by making an incision over the course of the nerve about the centre of the thigh. The skin, superficial structures, and deep fascia having been divided, the interval between the inner and outer hamstrings is to be defined, and these muscles pulled inward and outward with retractors. The nerve will be found a little to the inner side of the Biceps. It is to be separated from the surrounding structures, hooked up with the finger, and stretched by steady and continuous traction for two or three minutes. The sciatic nerve may also be stretched by what is known as the "dry" plan. The patient is laid on his back, the foot is extended, the leg flexed on the thigh, and the thigh strongly flexed on the abdomen. While the thigh is maintained in this position the leg is forcibly extended to its full extent and the foot as fully flexed on the leg.

The position of the external popliteal, close behind the tendon of the Biceps on the outer

side of the ham, should be remembered in subcutaneous division of the tendon. After it is divided a cord often rises up close beside it, which might be mistaken for a small undivided portion of the tendon, and the surgeon might be tempted to reintroduce his knife and divide it. This must never be done, as the cord is the external popliteal nerve, which becomes prominent as soon as the tendon is divided.

THE SYMPATHETIC NERVE.

The **Sympathetic Nervous System** consists of (1) a series of ganglia, connected together by intervening cords, extending from the base of the skull to the coccyx, one on each side of the middle line of the body, partly in front and partly on each side of the vertebral column; (2) of three great gangliated plexuses or aggregations of nerves and ganglia, situated in front of the spine in the thoracic, abdominal, and pelvic cavities respectively; (3) of smaller ganglia, situated in relation with the abdominal viscera; and (4) of numerous nerve-fibres. These latter are of two kinds: *communicating*, by which the ganglia communicate with each other and with the cerebro-spinal nerves; and *distributory*, supplying, in general, all the internal viscera and the coats of the blood-vessels.

Each **gangliated cord** may be traced upward from the base of the skull into its cavity by an ascending branch, which passes through the carotid canal, forms a plexus on the internal carotid artery, and communicates with the ganglia on the first and second divisions of the fifth nerve. According to some anatomists, the two cords are joined, at their cephalic extremities, by these ascending branches communicating in a small ganglion (the *ganglion of Ribes*), situated upon the anterior communicating artery. The ganglia of these cords are distinguished as cervical, dorsal, lumbar, and sacral, and except in the neck they correspond pretty nearly in number to the vertebræ against which they lie. They may be thus arranged:

Cervical portion	.	.	3 pairs of ganglia.
Dorsal	"	.	12 " "
Lumbar	"	.	4 " "
Sacral	"	.	4 or 5 " "

In the neck they are situated in front of the transverse processes of the vertebræ; in the dorsal region, in front of the heads of the ribs; in the lumbar region, on the sides of the bodies of the vertebræ; and in the sacral region, in front of the sacrum. As the two cords pass into the pelvis they converge and unite together in a single ganglion (*ganglion impar*) placed in front of the coccyx. Each ganglion may be regarded as a distinct centre, and, in addition to its branches of distribution, possesses also branches of communication which communicate with other ganglia and with the cerebro-spinal nerves.

The branches of communication between the ganglia are composed of gray and white nerve-fibres, the latter being continuous with those fibres of the spinal nerves which pass to the ganglia.

The branches of communication between the ganglia and the cerebro-spinal nerves also consist of a white and gray portion, the former proceeding from the spinal nerve *to* the ganglion, the latter passing *from* the ganglion to the spinal nerve, so that a double interchange takes place between the two systems.

The **three great gangliated plexuses** are situated in front of the spine in the thoracic, abdominal, and pelvic regions, and are named, respectively, the *cardiac*, the *solar* or *epigastric*, and the *hypogastric plexus*. They consist of collections of nerves and ganglia, the nerves being derived from the gangliated cords and from the cerebro-spinal nerves. They distribute branches to the viscera.

Smaller ganglia are also found lying amidst the nerves, some of them of microscopic size, in certain viscera—as, for instance, in the heart, the stomach, and the uterus. They serve as additional centres for the origin of nerve-fibres.

The *branches of distribution* derived from the gangliated cords, from the prevertebral plexuses, and also from the smaller ganglia, are principally destined for the blood-vessels and thoracic and abdominal viscera, supplying the involuntary

FIG. 473.—The sympathetic nerve.

muscular fibre of the coats of the vessels and the hollow viscera, and the secreting cells, as well as the muscular coats of the vessels in the glandular viscera.

In addition to these various divisions of the sympathetic, the ganglia connected with the three branches of the fifth cranial nerve are believed by some to constitute a part of the sympathetic system. These ganglia have already been described (page 763 *et seq.*).

THE GANGLIATED CORD.

Cervical Portion of the Gangliated Cord.

The cervical portion of the gangliated cord consists of three ganglia on each side, which are distinguished, according to their position, as the superior, middle, and inferior cervical.

The **Superior Cervical Ganglion**, the largest of the three, is placed opposite the second and third cervical vertebrae, and sometimes as low as the fourth or fifth. It is of a reddish-gray color, and usually fusiform in shape, sometimes broad, and occasionally constricted at intervals, so as to give rise to the opinion that it consists of the coalescence of several smaller ganglia; and it is usually believed that it is formed by the coalescence of the four ganglia, corresponding to the four upper cervical nerves. It is in relation, in front, with the sheath of the internal carotid artery and internal jugular vein; behind, it lies on the *Rectus capitis anticus major* muscle.

Its branches may be divided into superior, inferior, external, internal, and anterior.

The *superior branch* appears to be a direct prolongation of the ganglion. It is soft in texture and of a reddish color. It ascends by the side of the internal carotid artery, and, entering the carotid canal in the temporal bone, divides into two branches, which lie, one on the outer, and the other on the inner, side of that vessel.

The *outer branch*, the larger of the two, distributes filaments to the internal carotid artery and forms the *carotid plexus*.

The *inner branch* also distributes filaments to the internal carotid, and, continuing onward, forms the *cavernous plexus*.

The Carotid Plexus.

The carotid plexus is situated on the outer side of the internal carotid. Filaments from this plexus occasionally form a small gangliform swelling on the under surface of the artery, which is called the carotid ganglion. The carotid plexus communicates with the Gasserian ganglion, with the sixth nerve, and the sphenopalatine ganglion, and distributes filaments to the wall of the carotid artery and to the dura mater (Valentin), while in the carotid canal it communicates with Jacobson's nerve, the tympanic branch of the glosso-pharyngeal.

The *communicating branches with the sixth nerve* consist of one or two filaments which join that nerve as it lies upon the outer side of the internal carotid. Other filaments are also connected with the Gasserian ganglion. The communication with the sphenopalatine ganglion is effected by a branch, the *large deep petrosal*, which is given off from the plexus on the outer side of the artery, and which passes through the cartilage filling up the foramen lacerum medium, and joins the great superficial petrosal to form the Vidian nerve. The Vidian nerve then proceeds along the pterygoid or Vidian canal to the sphenopalatine ganglion. The communication with Jacobson's nerve is effected by two branches, one of which is called the *small deep petrosal nerve*, and the other the *long petrosal*.

The Cavernous Plexus.

The cavernous plexus is situated below and internal to that part of the internal carotid which is placed by the side of the sella Turcica in the cavernous sinus, and is formed chiefly by the internal division of the ascending branch from the superior cervical ganglion. It communicates with the third, the fourth, the ophthalmic division of the fifth, and the sixth nerves, and with the ophthalmic

FIG. 454.—Plan of the cervical portion of the sympathetic. (After Flower.)

ganglion, and distributes filaments to the wall of the internal carotid. The branch of communication with the third nerve joins it at its point of division; the branch to the fourth nerve joins it as it lies on the outer wall of the cavernous sinus; other filaments are connected with the under surface of the trunk of the ophthalmic nerve; and a second filament of communication joins the sixth nerve.

The filament of connection with the ophthalmic ganglion arises from the anterior part of the cavernous plexus; it accompanies the nasal nerve or continues forward as a separate branch.

The terminal filaments from the carotid and cavernous plexuses are prolonged along the internal carotid, forming plexuses which entwine round the cerebral and ophthalmic arteries; along the former vessels they may be traced on to the pia mater; along the latter, into the orbit, where they accompany each of the subdivisions of the vessel, a separate plexus passing, with the arteria centralis retinae, into the interior of the eyeball. The filaments prolonged on to the anterior communicating artery form a small ganglion, the *ganglion of Ribes*,¹ which serves, as mentioned above, to connect the sympathetic nerves of the right and left sides.

The inferior or descending branch of the superior cervical ganglion communicates with the middle cervical ganglion.

The external branches are numerous, and communicate with the cranial nerves and with the four upper spinal nerves. Sometimes the branch to the fourth spinal nerve may come from the cord connecting the upper and middle cervical ganglia. The branches of communication with the cranial nerves consist of delicate filaments, which pass from the superior cervical ganglion to the ganglion of the trunk of the pneumogastric and to the hypoglossal nerve. A separate filament from the cervical ganglion subdivides and joins the petrosal ganglion of the glosso-pharyngeal and the ganglion of the root of the pneumogastric in the jugular foramen.

The internal branches are three in number—the *pharyngeal*, *laryngeal*, and *superior cardiac nerve*. The *pharyngeal branches* pass inward to the side of the pharynx, where they join with branches from the glosso-pharyngeal, pneumogastric, and external laryngeal nerves to form the *pharyngeal plexus*. The *laryngeal branches* unite with the superior laryngeal nerve and its branches.

The *superior cardiac nerve* (*nervus superficialis cordis*) arises by two or more branches from the superior cervical ganglion, and occasionally receives a filament from the cord of communication between the first and second cervical ganglia. It runs down the neck behind the common carotid artery, lying upon the *Longus colli* muscle, and crosses in front of the inferior thyroid artery and recurrent laryngeal nerve.

The *right superior cardiac nerve*, at the root of the neck, passes either in front of or behind the subclavian artery, and along the arteria innominata, to the back part of the arch of the aorta, where it joins the deep cardiac plexus. This nerve, in its course, is connected with other branches of the sympathetic; about the middle of the neck it receives filaments from the external laryngeal nerve; lower down, one or two twigs from the pneumogastric; and as it enters the thorax it is joined by a filament from the recurrent laryngeal. Filaments from this nerve communicate with the thyroid branches from the middle cervical ganglion.

The *left superior cardiac nerve*, in the chest, runs by the side of the left common carotid artery and in front of the arch of the aorta to the superficial cardiac plexus, but occasionally it passes behind the aorta and terminates in the deep cardiac plexus.

The anterior branches ramify upon the external carotid artery and its branches, forming round each a delicate plexus, on the nerves composing which small ganglia are occasionally found. These ganglia have been named, according to their position, *intercarotid*² (placed at the angle of bifurcation of the common carotid), *lingual*, *temporal*, and *pharyngeal*. The plexuses accompanying some of these

¹ The existence of this ganglion is doubted by some observers.

² This ganglion is of the same structure as the coccygeal gland (Luschka).

arteries have important communications with other nerves. That surrounding the external carotid is connected with the branch of the facial nerve to the stylo-hyoid muscle; that surrounding the facial communicates with the submaxillary ganglion by one or two filaments; and that accompanying the middle meningeal artery sends offsets which pass to the otic ganglion and to the intumescencia ganglioformis of the facial nerve (external petrosal).

The **Middle Cervical Ganglion** (*thyroid ganglion*) is the smallest of the three cervical ganglia, and is occasionally altogether wanting. It is placed opposite the sixth cervical vertebra, usually upon, or close to, the inferior thyroid artery; hence the name, "thyroid ganglion," assigned to it by Haller. It is probably formed by the coalescence of two ganglia corresponding to the fifth and sixth cervical nerves.

Its *superior branches* ascend to communicate with the superior cervical ganglion.

Its *inferior branches* descend to communicate with the inferior cervical ganglion.

Its *external branches* pass outward to join the fifth and sixth spinal nerves. These branches are not constantly found.

Its *internal branches* are the thyroid and the middle cardiac nerve.

The *thyroid branches* are small filaments which accompany the inferior thyroid artery to the thyroid gland; they communicate, on the artery, with the superior cardiac nerve, and, in the gland, with branches from the recurrent and external laryngeal nerves.

The *middle cardiac nerve* (*nervus cardiacus magnus*), the largest of the three cardiac nerves, arises from the middle cervical ganglion or from the cord between the middle and inferior ganglia. On the right side it descends behind the common carotid artery, and at the root of the neck passes either in front of or behind the subclavian artery; it then descends on the trachea, receives a few filaments from the recurrent laryngeal nerve, and joins the deep cardiac plexus. In the neck it communicates with the superior cardiac and recurrent laryngeal nerves. On the left side the middle cardiac nerve enters the chest between the left carotid and subclavian arteries, and joins the left side of the deep cardiac plexus.

The **Inferior Cervical Ganglion** is situated between the base of the transverse process of the last cervical vertebra and the neck of the first rib on the inner side of the superior intercostal artery. Its form is irregular; it is larger in size than the preceding, and frequently joined with the first thoracic ganglion. It is probably formed by the coalescence of two ganglia which correspond to the two last cervical nerves.

Its *superior branches* communicate with the middle cervical ganglion.

Its *inferior branches* descend, some in front of, others behind, the subclavian artery, to join the first thoracic ganglion.

Its *internal branch* is the inferior cardiac nerve.

The *inferior cardiac nerve* (*nervus cardiacus minor*) arises from the inferior cervical or first thoracic ganglion. It passes down behind the subclavian artery and along the front of the trachea to join the deep cardiac plexus. It communicates freely behind the subclavian artery with the recurrent laryngeal and middle cardiac nerves.

The *external branches* consist of several filaments, some of which communicate with the seventh and eighth spinal nerves; others accompany the vertebral artery along the vertebral canal, forming a plexus round the vessel, supplying it with filaments, and communicating with the cervical spinal nerves as high as the fourth.

Thoracic Portion of the Gangliated Cord.

The thoracic portion of the gangliated cord consists of a series of ganglia which usually correspond in number to that of the vertebræ, but, from the occasional coalescence of two, their number is uncertain. These ganglia are placed on each side of the spine, resting against the heads of the ribs and covered by the

pleura costalis; the last two are, however, anterior to the rest, being placed on the side of the bodies of the eleventh and twelfth dorsal vertebræ. The ganglia are small in size and of a grayish color. The first, larger than the rest, is of an elongated form and frequently blended with the last cervical. They are connected together by cord-like prolongations from their substance.

The *external branches* from each ganglion, usually two in number, communicate with each of the dorsal spinal nerves.

The *internal branches from the six upper ganglia* are very small; they supply filaments to the thoracic aorta and its branches, besides small branches to the bodies of the vertebræ and their ligaments. Branches from the third and fourth, and sometimes also from the first and second ganglia, form part of the posterior pulmonary plexus.

The *internal branches from the six lower ganglia* are large and white in color; they distribute filaments to the aorta and unite to form the three splanchnic nerves. These are named the *great*, the *lesser*, and the *smallest* or *renal splanchnic*.

The *great splanchnic nerve* is of a white color, firm in texture, and bears a marked contrast to the ganglionic nerves. It is formed by branches from the thoracic ganglia between the sixth and tenth, receiving filaments (according to Dr. Beck) from all the thoracic ganglia above the sixth. These roots unite to form a large round cord of considerable size. It descends obliquely inward in front of the bodies of the vertebræ along the posterior mediastinum, perforates the crus of the Diaphragm, and terminates in the semilunar ganglion, distributing filaments to the renal and suprarenal plexus.

The *lesser splanchnic nerve* is formed by filaments from the tenth and eleventh ganglia and from the cord between them. It pierces the Diaphragm with the preceding nerve and joins the celiac plexus. It communicates in the chest with the great splanchnic nerve, and occasionally sends filaments to the renal plexus.

The *smallest, or renal, splanchnic nerve* arises from the last ganglion, and, piercing the Diaphragm, terminates in the renal plexus and lower part of the celiac plexus. It occasionally communicates with the preceding nerve.

A striking analogy appears to exist between the splanchnic and the cardiac nerves. The cardiac nerves are three in number; they arise from the three cervical ganglia, and are distributed to a large and important organ in the thoracic cavity. The splanchnic nerves, also three in number, are connected probably with all the dorsal ganglia, and are distributed to important organs in the abdominal cavity.

The Lumbar Portion of the Gangliated Cord.

The lumbar portion of the gangliated cord is situated in front of the vertebral column along the inner margin of the Psoas muscle. It consists usually of four ganglia, connected together by interganglionic cords. The ganglia are of small size, of a grayish color, shaped like a barleycorn, and placed much nearer the median line than the thoracic ganglia.

The *superior and inferior branches of the lumbar ganglia* serve as communicating branches between the chain of ganglia in this region. They are usually single and of a white color.

The *external branches* communicate with the lumbar spinal nerves. From the situation of the lumbar ganglia these branches are longer than in the other regions. They are usually two in number from each ganglion, but their connection with the spinal nerves is not so uniform as in other regions. They accompany the lumbar arteries around the sides of the bodies of the vertebræ, passing beneath the fibrous arches from which some of the fibres of the Psoas muscle arise.

Of the *internal branches*, some pass inward, in front of the aorta, and help to form the aortic plexus. Other branches descend in front of the common iliac arteries, and join over the promontory of the sacrum, helping to form the hypogastric plexus. Numerous delicate filaments are also distributed to the bodies of the vertebræ and the ligaments connecting them.

Pelvic Portion of the Gangliated Cord.

The pelvic portion of the gangliated cord is situated in front of the sacrum along the inner side of the anterior sacral foramina. It consists of four or five small ganglia on each side, connected together by interganglionic cords. Below, these cords converge and unite on the front of the coccyx by means of a small ganglion (the *coccygeal ganglion* or *ganglion impar*).

The *superior* and *inferior branches* are the cords of communication between the ganglia above and below.

The *external branches*, exceedingly short, communicate with the sacral nerves. They are two in number from each ganglion. The coccygeal nerve communicates either with the last sacral or coccygeal ganglion.

The *internal branches* communicate, on the front of the sacrum, with the corresponding branches from the opposite side; some, from the first two ganglia, pass to join the pelvic plexus, and others form a plexus which accompanies the middle sacral artery and sends filaments to the coccygeal gland.

THE GREAT PLEXUSES OF THE SYMPATHETIC.

The great plexuses of the sympathetic are the large aggregations of nerves and ganglia, above alluded to, situated in the thoracic, abdominal, and pelvic cavities respectively. From them are derived the branches which supply the viscera.

The Cardiac Plexus.

The cardiac plexus is situated at the base of the heart, and is divided into a *superficial part*, which lies in the concavity of the arch of the aorta, and a *deep part*, which lies between the trachea and aorta.

The **great or deep cardiac plexus** (*plexus magnus profundus*, Scarpa) is situated in front of the trachea at its bifurcation, above the point of division of the pulmonary artery and behind the arch of the aorta. It is formed by the cardiac nerves derived from the cervical ganglia of the sympathetic and the cardiac branches of the recurrent laryngeal and pneumogastric. The only cardiac nerves which do not enter into the formation of this plexus are the left superior cardiac nerve and the left inferior cervical cardiac branch from the pneumogastric.

The branches from the *right side* of this plexus pass, some in front of, and others behind, the right pulmonary artery; the former, the more numerous, transmit a few filaments to the anterior pulmonary plexus, and are then continued onward to form part of the anterior coronary plexus; those behind the pulmonary artery distribute a few filaments to the right auricle, and are then continued onward to form part of the posterior coronary plexus.

The branches from the *left side* of the deep cardiac plexus distribute a few filaments to the superficial cardiac plexus, to the left auricle of the heart, and to the anterior pulmonary plexus, and then pass on to form the greater part of the posterior coronary plexus.

The **superficial (anterior) cardiac plexus** lies beneath the arch of the aorta, in front of the right pulmonary artery. It is formed by the left superior cardiac nerve, the left (and occasionally the right) inferior cervical cardiac branches of the pneumogastric, and filaments from the deep cardiac plexus. A small ganglion (*cardiac ganglion of Wrisberg*) is occasionally found connected with these nerves at their point of junction. This ganglion, when present, is situated immediately beneath the arch of the aorta, on the right side of the ductus arteriosus. The superficial cardiac plexus forms the chief part of the anterior coronary plexus, and several filaments pass along the pulmonary artery to the left anterior pulmonary plexus.

The **posterior coronary plexus** is chiefly formed by filaments prolonged from the left side of the deep cardiac plexus, and by a few from the right side. It surrounds the branches of the coronary artery at the back of the heart, and its

filaments are distributed with those vessels to the muscular substance of the ventricles.

The **anterior coronary plexus** is formed chiefly from the superficial cardiac plexus, but receives filaments from the deep cardiac plexus. Passing forward between the aorta and pulmonary artery, it accompanies the left coronary artery on the anterior surface of the heart.

Valentin has described nervous filaments ramifying under the endocardium; and Remak has found, in several mammalia, numerous small ganglia on the cardiac nerves, both on the surface of the heart and in its muscular substance.

The Epigastric or Solar Plexus (Figs. 473, 475).

The **Epigastric or Solar plexus** supplies all the viscera in the abdominal cavity. It consists of a great network of nerves and ganglia, situated behind the stomach and in front of the aorta and crura of the Diaphragm. It surrounds the celiac axis and root of the superior mesenteric artery, extending downward as low as the pancreas and outward to the suprarenal capsules. This plexus, and the ganglia connected with it, receive the great splanchnic nerve of both sides, and some filaments from the right pneumogastric. It distributes filaments which accompany, under the name of plexuses, all the branches from the front of the abdominal aorta.

The **semilunar ganglia of the solar plexus**, two in number, one on each side, are the largest ganglia in the body. They are large irregular gangliform masses formed by the aggregation of smaller ganglia, having interspaces between them. They are situated in front of the crura of the Diaphragm, close to the suprarenal capsules: the one on the right side lies beneath the inferior vena cava; the upper part of each ganglion is joined by the greater splanchnic nerve, and to the inner side of each the branches of the solar plexus are connected.

From the epigastric or solar plexus are derived the following:

Phrenic or Diaphragmatic plexus.

Suprarenal plexus.

Renal plexus.

Spermatic plexus.

Celiac plexus { Gastric plexus.
Splenic plexus.
Hepatic plexus.

Superior mesenteric plexus.

Aortic plexus.

The **phrenic plexus** accompanies the phrenic artery to the Diaphragm, which it supplies, some filaments passing to the suprarenal capsule. It arises from the upper part of the semilunar ganglion, and is larger on the right than on the left side. It receives one or two branches from the phrenic nerve. In connection with this plexus, on the right side, at its point of junction with the phrenic nerve, is a small ganglion (*ganglion diaphragmaticum*). This ganglion is placed on the under surface of the Diaphragm, near the suprarenal capsule. Its branches are distributed to the inferior vena cava, suprarenal capsule, and hepatic plexus. There is no ganglion on the left side.

The **suprarenal plexus** is formed by branches from the solar plexus, from the semilunar ganglion, and from the phrenic and great splanchnic nerves, a ganglion being formed at the point of junction of the latter nerve. It supplies the suprarenal capsule. The branches of this plexus are remarkable for their large size in comparison with the size of the organ they supply.

The **renal plexus** is formed by filaments from the solar plexus, the outer part of the semilunar ganglion, and the aortic plexus. It is also joined by filaments from the lesser and smallest splanchnic nerves. The nerves from these sources, fifteen or twenty in number, have numerous ganglia developed upon them. They accompany the branches of the renal artery into the kidney, some filaments on the right side being distributed to the inferior vena cava, and others to the spermatic plexus on both sides.

The **spermatic plexus** is derived from the renal plexus, receiving branches from the aortic plexus. It accompanies the spermatic vessels to the testes.

FIG. 455.—Lumbar portion of the gangliated cord, with the solar and hypogastric plexuses. (After Henle.)

In the female the **ovarian plexus** is distributed to the ovaries and fundus of the uterus.

The **cœliac plexus**, of large size, is a direct continuation from the solar plexus: it surrounds the cœliac axis and subdivides into the gastric, hepatic, and splenic

plexuses. It receives branches from the lesser splanchnic nerves, and, on the left side, a filament from the right pneumogastric.

The *gastric* or *coronary plexus* accompanies the gastric artery along the lesser curvature of the stomach, and joins with branches from the left pneumogastric nerve. It is distributed to the stomach.

The *hepatic plexus*, the largest offset from the celiac plexus, receives filaments from the left pneumogastric and right phrenic nerves. It accompanies the hepatic artery, ramifying in the substance of the liver upon its branches and upon those of the vena portæ.

Branches from this plexus accompany all the divisions of the hepatic artery. Thus there is a *pyloric plexus* accompanying the pyloric branch of the hepatic, which joins with the gastric plexus and pneumogastric nerves. There is also a *gastro-duodenal plexus*, which subdivides into the pancreatico-duodenal plexus, which accompanies the pancreatico-duodenal artery, to supply the pancreas and duodenum, joining with branches from the mesenteric plexus; and a *gastro-epiploic plexus*, which accompanies the right gastro-epiploic artery along the greater curvature of the stomach and anastomoses with branches from the splenic plexus. A *cystic plexus*, which supplies the gall-bladder, also arises from the hepatic plexus near the liver.

The *splenic plexus* is formed by branches from the celiac plexus, the left semilunar ganglia, and from the right pneumogastric nerve. It accompanies the splenic artery and its branches to the substance of the spleen, giving off, in its course, filaments to the pancreas (*pancreatic plexus*) and the *left gastro-epiploic plexus*, which accompanies the gastro-epiploica sinistra artery along the convex border of the stomach.

The *superior mesenteric plexus* is a continuation of the lower part of the great solar plexus, receiving a branch from the junction of the right pneumogastric nerve with the celiac plexus. It surrounds the superior mesenteric artery, which it accompanies into the mesentery, and divides into a number of secondary plexuses, which are distributed to all the parts supplied by the artery—viz. pancreatic branches to the pancreas; intestinal branches, which supply the whole of the small intestine; and ileo-colic, right colic, and middle colic branches, which supply the corresponding parts of the great intestine. The nerves composing this plexus are white in color and firm in texture, and have numerous ganglia developed upon them near their origin.

The *aortic plexus* is formed by branches derived, on each side, from the solar plexus and the semilunar ganglia, receiving filaments from some of the lumbar ganglia. It is situated upon the sides and front of the aorta, between the origins of the superior and inferior mesenteric arteries. From this plexus arise part of the spermatic, the inferior mesenteric, and the hypogastric plexuses; and it distributes filaments to the inferior vena cava.

The *inferior mesenteric plexus* is derived chiefly from the left side of the aortic plexus. It surrounds the inferior mesenteric artery, and divides into a number of secondary plexuses, which are distributed to all the parts supplied by the artery—viz. the left colic and sigmoid plexuses, which supply the descending and sigmoid flexure of the colon; and the superior hæmorrhoidal plexus, which supplies the upper part of the rectum and joins in the pelvis with branches from the pelvic plexus.

The Hypogastric Plexus.

The *Hypogastric Plexus* supplies the viscera of the pelvic cavity. It is situated in front of the promontory of the sacrum, between the two common iliac arteries, and is formed by the union of numerous filaments, which descend on each side from the aortic plexus and from the lumbar ganglia. This plexus contains no ganglia, and bifurcates, below, into two lateral portions, which form the *pelvic plexuses*.

The Pelvic Plexus.

The **Pelvic Plexus** (sometimes called *inferior hypogastric*) supplies the viscera of the pelvic cavity, is situated at the side of the rectum and bladder in the male, and at the side of the rectum, vagina, and bladder in the female. It is formed by a continuation of the hypogastric plexus, by branches from the second, third, and fourth sacral nerves, and by a few filaments from the first two sacral ganglia. At the point of junction of these nerves small ganglia are found. From this plexus numerous branches are distributed to all the viscera of the pelvis. They accompany the branches of the internal iliac artery.

The **inferior hæmorrhoidal plexus** arises from the back part of the pelvic plexus. It supplies the rectum, joining with branches of the superior hæmorrhoidal plexus.

The **vesical plexus** arises from the fore part of the pelvic plexus. The nerves composing it are numerous, and contain a large proportion of spinal nerve-fibres. They accompany the vesical arteries, and are distributed at the side and base of the bladder. Numerous filaments also pass to the vesiculæ seminales and vas deferens; those accompanying the vas deferens join, on the spermatic cord, with branches from the spermatic plexus.

The **prostatic plexus** is continued from the lower part of the pelvic plexus. The nerves composing it are of large size. They are distributed to the prostate gland, vesiculæ seminales, and erectile structure of the penis. The nerves supplying the erectile structure of the penis consist of two sets, the small and large cavernous nerves. They are slender filaments, which arise from the fore part of the prostatic plexus, and, after joining with branches from the internal pudic nerve, pass forward beneath the pubic arch.

The *small cavernous nerves* perforate the fibrous covering of the penis near its roots.

The *large cavernous nerve* passes forward along the dorsum of the penis, joins with the dorsal branch of the pudic nerve, and is distributed to the corpus cavernosum and spongiosum.

The **vaginal plexus** arises from the lower part of the pelvic plexus. It is lost on the walls of the vagina, being distributed to the erectile tissue at its anterior part and to the mucous membrane. The nerves composing this plexus contain, like the vesical, a large proportion of spinal nerve-fibres.

The **uterine plexus** arises from the upper part of the pelvic plexus above the point where the branches from the sacral nerves join the plexus. Its branches accompany the uterine arteries to the side of the organ between the layers of the broad ligament, and are distributed to the cervix and lower part of the body of the uterus, penetrating its substance.

Other filaments pass separately to the body of the uterus and Fallopian tube.

Branches from the plexus accompany the uterine arteries into the substance of the uterus. Upon these filaments ganglionic enlargements are found.

THE ORGANS OF SENSE.

THE Organs of the Senses are five in number—viz. those of Touch, of Taste, of Smell, of Hearing, and of Sight. The skin, which is the principal seat of the sense of touch, has been described in the chapter on General Anatomy.

THE TONGUE.

The Tongue is the organ of the special sense of taste. It is situated in the floor of the mouth, in the interval between the two lateral portions of the body of the lower jaw.

Its base or root is directed backward, and connected with the os hyoides by the Hyo-glossi and Genio-hyo-glossi muscles and the hyo-glossal membrane; with

FIG. 476.—Upper surface of the tongue.

the epiglottis by three folds of mucous membrane which form the *glosso-epiglottic ligaments*; with the soft palate by means of the anterior pillars of the fauces; and with the pharynx by the Superior constrictor and the mucous membrane. Its apex or tip, thin and narrow, is directed forward against the inner surface of the lower incisor teeth. The under surface of the tongue is connected with the lower jaw by the Genio-hyo-glossi muscles; from its sides the mucous membrane is reflected to the inner surface of the gums; and in front a distinct fold of that membrane, the *frænum lingue*, is formed beneath its under surface.

The *tip* of the tongue, part of the under surface, its sides and dorsum, are free.

The dorsum of the tongue is convex, marked along the middle line by a raphe, which divides it into symmetrical halves; this raphe terminates behind, about an inch from the base of the organ, in a depression, the *foramen cæcum*. The anterior two-thirds of this surface are rough and covered with papillæ; the posterior third is smoother, and covered by the projecting orifices of numerous muciparous glands.

Structure of the Tongue.—The tongue is partly invested by mucous membrane and a submucous fibrous layer. It consists of symmetrical halves, separated from each other, in the middle line, by a fibrous septum. Each half is composed of muscular fibres arranged in various directions, containing much interposed fat, and supplied by vessels and nerves.

The **mucous membrane** invests the entire extent of the free surface of the tongue. On the dorsum it is thicker behind than in front, and is continuous with the sheath of the muscles attached to it, through the submucous fibrous layer. On the under surface of the organ it can be traced on each side of the frænum through the ducts of the submaxillary and the sublingual glands. As it passes over the borders of the organ it gradually assumes its papillary character.

The **structure of the mucous membrane of the tongue** differs in different parts. That covering the under surface of the organ is thin, smooth, and identical in structure with that lining the rest of the oral cavity. The mucous membrane on the anterior part of the dorsum of the tongue is thin and intimately adherent to the muscular tissue, whilst that at the root is much thicker and looser. It consists

FIG. 477.—The three kinds of papillæ, magnified.

of a layer of connective tissue, the *corium* or *mucosa*, supporting numerous *papillæ* and covered, as well as the papillæ, with *epithelium*.

The epithelium is of the scaly variety, like that of the epidermis. It covers the free surface of the tongue, as may be easily demonstrated by maceration or boiling, when it can be easily detached entire: it is much thinner than on the skin: the intervals between the large papillæ are not filled up by it, but each papilla has a separate investment from root to summit. The deepest cells may sometimes be detached as a separate layer, corresponding to the rete mucosum, but they never contain coloring matter.

The *corium* consists of a dense feltwork of fibrous connective tissue, with numerous elastic fibres, firmly connected with the fibrous tissue forming the septa between the muscular bundles of the tongue. It contains the ramifications of the numerous vessels and nerves from which the papillæ are supplied, large plexuses of lymphatic vessels, and the glands of the tongue.

The Papillæ of the Tongue.—These are papillary projections of the corium. They are thickly distributed over the anterior two-thirds of its upper surface, giving

to it its characteristic roughness. The varieties of papillæ met with are—the papillæ maximæ (*circumvallatæ*), papillæ mediæ (*fungiformes*), papillæ minimæ (*conicæ* or *filiformes*), and papillæ simplices.

The *papillæ maximæ* (*circumvallatæ*) are of large size, and vary from eight to twelve in number. They are situated at the back part of the dorsum of the tongue, near its base, forming a row on each side, which, running backward and inward, meet in the middle line, like the two lines of the letter V inverted. Each papilla consists of a projection of mucous membrane from $\frac{1}{10}$ to $\frac{1}{2}$ of an inch wide, attached to the bottom of a cup-shaped depression of the mucous membrane; the papilla is in shape like a truncated cone, the smaller end being directed downward and attached to the tongue, the broader part or base projecting on the surface and being studded with numerous small secondary papillæ, which, however, are covered by a smooth layer of the epithelium. The cup-shaped depression forms a kind of fossa round the papilla, having a circular margin of about the same elevation covered with smaller papillæ. At the point of junction of the two rows of papillæ is the deep depression, the *foramen cæcum*, mentioned above.

The *papillæ mediæ* (*fungiformes*), more numerous than the preceding, are scattered irregularly and sparingly over the dorsum of the tongue, but are found chiefly at its sides and apex. They are easily recognized among the other papillæ, by their large size, rounded eminences, and deep-red color. They are narrow at their attachment to the tongue, but broad and rounded at their free extremities, and covered with secondary papillæ. Their epithelial investment is very thin.

The *papillæ minimæ* (*conicæ* or *filiformes*) cover the anterior two-thirds of the dorsum of the tongue. They are very minute, more or less conical or filiform in shape, and arranged in lines corresponding in direction with the two rows of the papillæ *circumvallatæ*, excepting at the apex of the organ, where their direction is transverse. They have projecting from their apices numerous filiform processes or secondary papillæ, which are of a whitish tint, owing to the thickness and density of the epithelium of which they are composed, and which has here undergone a peculiar modification, the cells having become cornified and elongated into dense, imbricated, brush-like processes. They contain also a number of elastic fibres, which render them firmer and more elastic than the papillæ of mucous membrane generally.

Simple papillæ, similar to those of the skin, cover the whole of the mucous membrane of the tongue, as well as the larger papillæ. They consist of closely-set, microscopic elevations of the corium, containing a capillary loop, covered by a layer of epithelium.

Structure of the Papillæ.—The papillæ apparently resemble in structure those of the cutis, consisting of a cone-shaped projection of connective tissue, covered with a thick layer of squamous epithelium, and contain one or more capillary loops, amongst which nerves are distributed in great abundance. If the epithelium is removed, it will be found that they are not simple elevations like the papillæ of the skin, for the surface of each is studded with minute conical processes of the mucous membrane, which form secondary papillæ (Todd and Bowman). In the papillæ *circumvallatæ* the nerves are numerous and of large size; in the papillæ *fungiformes* they are also numerous, and terminate in a plexiform network, from which brush-like branches proceed; in the papillæ *filiformes* their

FIG. 478.—Circumvallate papilla of tongue of rabbit, showing position of taste-goblets. (Stöhr.) a. Duct of gland. d. Serous gland. g. Taste-goblets. t. Primary septa, and p. secondary septa of papillæ. n. Medullated nerve. m. Muscular fibres.

mode of termination is uncertain. Buried in the epidermis of the papillæ circumvallatæ, and in some of the fungiformes, certain peculiar bodies called *taste-goblets* have been described.¹ They are flask-like in shape, their broad base resting on the corium, and their neck opening by an orifice between the cells of the epithelium. They are formed by two kinds of cells: the external (cortical) are arranged in several layers; they are long and flattened, with tapering ends, and in contact by their edges, the tapering extremities extending from the base to the apex of the organ. They thus enclose the central cells (gustatory cells), which are spindle-shaped and have a large spherical nucleus about the middle of the cell. Both extremities are filamentous; the inner process is described as continuous with the terminal fibril of a nerve, while the outer one projects as an extremely fine hair through the orifice of the taste-goblet.²

FIG. 479.—Taste-goblets. a, Central cell. b, Cortical cell.

by a fasciculus of muscular fibre derived from the Stylo-glossus and Inferior lingualis. It is from half an inch to nearly an inch long and about the third of an inch broad. It has from four to six ducts, which open on the under surface of the apex.

The *serous glands* occur only at the back of the tongue in the neighborhood

FIG. 480.—Under surface of tongue, showing position and relations of gland of Blandin and Nuhn. (From a preparation in the Museum of the Royal College of Surgeons.)

of the taste-goblets, their ducts opening for the most part into the fossæ of the circumvallate papillæ. These glands are racemose, the duct branching into several minute ducts, which terminate in alveoli lined by a single layer of more or less columnar epithelium. Their secretion is of a watery nature, and probably

¹ These bodies are also found in considerable numbers at the side of the base of the tongue, just in front of the anterior pillars of the fauces.

² See Englemann, in Stricker's *Handbook* (New Syd. Soc. Trans.), vol. iii. p. 2.

assists in the distribution of the substance to be tasted over the taste-area (Ebner).

The Lymphoid Follicles.—The *lymphoid tissue* is situated, for the most part at the back of the tongue, between the epiglottis and the circumvallate papillæ, and is collected at numerous points into distinct masses known as *lymphoid follicles*. Here and there in this situation are depressions in the mucous membrane, surrounded by nodules of lymphoid tissue, similar to the structure found in the tonsil: into them open some of the ducts of the mucous glands.

The *fibrous septum* consists of a vertical layer of fibrous tissue, extending throughout the entire length of the middle line of the tongue, from the base to the

FIG. 481.—Under surface of the tongue, showing the distribution of nerves to this organ. (From a preparation in the Museum of the Royal College of Surgeons.)

apex, though not quite reaching the dorsum. It is thicker behind than in front, and occasionally contains a small fibro-cartilage about a quarter of an inch in length. It is well displayed by making a vertical section across the organ.

The **Hyo-glossal membrane** is a strong fibrous lamina which connects the under surface of the base of the tongue to the body of the hyoid bone. This membrane receives, in front, some of the fibres of the Genio-hyo-glossi.

Vessels of the Tongue.—The *arteries of the tongue* are derived from the lingual, the facial, and ascending pharyngeal. The *veins of the tongue* accompany the arteries.

Muscles of the Tongue.—The muscular fibres of the tongue run in various directions. These fibres are divided into two sets, Extrinsic and Intrinsic.

The *Extrinsic muscles of the tongue* are those which have their origin external

to it, and only their terminal fibres contained in the substance of the organ. They are the Stylo-glossus, the Hyo-glossus, the Palato-glossus, the Genio-hyo-glossus, and part of the Superior constrictor of the pharynx (Pharyngo-glossus).

The *Intrinsic muscles* are those which are contained entirely within the tongue and form the greater part of its substance. Both sets have been already described (page 417).

The *lymphatic vessels from the tongue* pass to one or two small glands situated on the Hyo-glossus muscle in the submaxillary region, and from thence to the deep glands of the neck.

The *nerves of the tongue* are four in number in each half: the lingual branch of the fifth, which is distributed to the papillæ at the fore part and sides of the tongue; the lingual branch of the glosso-pharyngeal, which is distributed to the mucous membrane at the base and side of the tongue and to the papillæ circumvallatæ; the hypoglossal nerve, which is distributed to the muscular substance of the tongue; and the chorda tympani to the Lingualis muscle. Sympathetic filaments also pass to the tongue from the nervi molles on the lingual and other arteries supplying it. The glosso-pharyngeal branch is the special nerve of the sense of taste, the lingual (gustatory) is the nerve of common sensation, and the hypoglossal is the motor nerve of the tongue, except for the Inferior lingualis, which is supplied by the chorda tympani.

Surgical Anatomy.—The diseases to which the tongue is liable are numerous, and its surgical anatomy of importance, since any or all the structures of which it is composed—muscles, connective tissue, mucous membrane, glands, vessels, nerves, and lymphatics—may be the seat of morbid changes. It is not often the seat of congenital defects, though a few cases of vertical cleft have been recorded, and it is occasionally, though much more rarely than is commonly supposed, the seat of "tongue-tie," from shortness of the frænum. (See page 556.)

There is, however, one condition which must be regarded as congenital, though it does not sometimes evidence itself until a year or two after birth, which is not uncommon. This is an enlargement of the tongue which is due primarily to a dilatation of the lymph-channels and a greatly increased development of the lymphatic tissue throughout the tongue. This is often aggravated by inflammatory changes induced by injury or exposure, and the tongue may assume enormous dimensions and hang out of the mouth, giving the child an imbecile expression. The treatment consists in excising a V-shaped portion and bringing the cut surfaces together with deeply-placed silver sutures. Compression has been resorted to in some cases and with success, but it is difficult to apply. Acute inflammation of the tongue, which may be caused by injury and the introduction of some septic or irritating matter, is attended by great swelling from infiltration of its connective tissue, which is in considerable quantity. This renders the patient incapable of swallowing or speaking, and may seriously impede respiration. It may run on to suppuration and the formation of an acute abscess. Chronic abscess, which has been mistaken for cancer, may also occur in the substance of the tongue.

The mucous membrane of the tongue may become chronically inflamed, and presents different appearances in different stages of the disease, to which the terms leucoplakia, psoriasis, and ichthyosis have been given.

The tongue, being very vascular, is often the seat of nœvoid growths, and these have a tendency to grow rapidly.

The tongue is frequently the seat of ulceration, which may arise from many causes, as from the irritation of jagged teeth, dyspepsia, tubercle, syphilis, and cancer. Of these the cancerous ulcer is the most important, and probably also the most common. The variety is the squamous epithelioma, which soon develops into an ulcer with an indurated base. It produces great pain, which speedily extends to all parts supplied with sensation by the fifth nerve, especially to the region of the ear. The pain in these cases is conducted to the ear and temporal region by the lingual nerve, and from it to the other branches of the inferior maxillary nerve, especially the auriculo-temporal. Possibly pain in the ear itself may be due to implication of the fibres of the glosso-pharyngeal nerve, which by its tympanic branch is conducted to the tympanic plexus.

Cancer of the tongue may necessitate removal of a part or the whole of the organ, and many different methods have been adopted for its excision. It may be removed from the mouth by the éraseur or the scissors. Probably the better method is by the scissors, usually known as Whitehead's method. The mouth is widely opened with a gag, the tongue transfixed with a stout silk ligature, by which to hold and make traction on it and the reflection of mucous membrane from the tongue to the jaw, and the insertion of the Genio-hyo-glossus first divided with a pair of curved blunt scissors. The Palato-glossus is also divided. The tongue can now be pulled well out of the mouth. The base of the tongue is cut through by a series of short snips, each bleeding vessel being dealt with as soon as divided, until the situation of the ranine artery is reached. The remaining undivided portion of tissue is to be seized with a pair of Wells's forceps, the tongue removed, and the vessel secured. In the event of the ranine artery being

accidentally injured hæmorrhage can be at once controlled by passing two fingers over the dorsum of the tongue as far as the epiglottis and dragging the root of the tongue forcibly forward.

In cases where the disease is confined to one side of the tongue this operation may be modified by splitting the tongue down the centre and removing only the affected half. In cases where the submaxillary glands are involved Kocher's operation should be performed. He removes the tongue from the neck, having performed a preliminary tracheotomy, by an incision from near the lobule of the ear, down the anterior border of the Sterno-mastoid to the level of the great cornu of the hyoid bone, then forward to the body of the hyoid bone, and upward to near the symphysis of the jaw. The lingual artery is now secured, and by a careful dissection the submaxillary lymphatic glands and the tongue removed. Regnoli advocated the removal of the tongue by a semilunar incision in the submaxillary triangle along the line of the lower jaw, and a vertical incision from the centre of the semilunar one backward to the hyoid bone. Care must be taken not to carry the first incision too far backward, so as to wound the facial arteries. The tongue is thus reached through the floor of the mouth, pulled out through the external incision, and removed with the *cérasseur* or knife. The great objection to this operation is that all the muscles which raise the hyoid bone and larynx are divided, and that therefore the movements of deglutition and respiration are interfered with.

Finally, where both sides of the floor of the mouth are involved in the disease, or where very free access is required on account of the extension backward of the disease to the pillars of the fauces and the tonsil, or where the lower jaw is involved, the operation recommended by Syme must be performed. This is done by an incision through the central line of the lip, across the chin, and down as far as the hyoid bone. The lower jaw is sawn through at the symphysis, and the two halves of the bone forcibly separated from each other. The mucous membrane is separated from the bone, and the Genio-hyo-glossi detached from the bone, and the Hyo-glossi divided. The tongue is then drawn forward and removed close to its attachment to the hyoid bone. Any glands which are enlarged can be removed, and if the bone is implicated in the disease, it can also be removed by freeing it from the soft parts externally and internally, and making a second section with the saw beyond the diseased part.

Formerly many surgeons before removing the tongue performed a preliminary tracheotomy: (1) to prevent blood entering the air-passages; and (2) to allow the patient to breathe through the tube and not inspire air which had passed over a sloughy wound, and which was loaded with septic organisms and likely to induce septic pneumonia. By the judicious use of iodoform this secondary evil may be obviated, and the preliminary tracheotomy is now usually dispensed with.

THE NOSE.

The nose is the special organ of the sense of smell: by means of the peculiar properties of its nerves it protects the lungs from the inhalation of deleterious gases and assists the organ of taste in discriminating the properties of food.

FIGS. 482, 483.—Cartilages of the nose.

The organ of smell consists of two parts—one external, the *nose*; the other internal, the *nasal fossæ*.

The *nose* is the more anterior and prominent part of the organ of smell. It is of a triangular form, directed vertically downward, and projects from the centre

of the face immediately above the upper lip. Its summit or root is connected directly with the forehead. Its inferior part, the base of the nose, presents two elliptical orifices, the nostrils, separated from each other by an antero-posterior septum, the *columna*. The margins of these orifices are provided with a number of stiff hairs, or *vibrissæ*, which arrest the passage of foreign substances carried with the current of air intended for respiration. The lateral surfaces of the nose form, by their union, the *dorsum*, the direction of which varies considerably in different individuals. The dorsum terminates below in a rounded eminence, the *lobe of the nose*.

The nose is composed of a framework of bones and cartilages, the latter being slightly acted upon by certain muscles. It is covered externally by the integument, internally by mucous membrane, and supplied with vessels and nerves.

The *bony framework* occupies the upper part of the organ: it consists of the nasal bones and the nasal processes of the superior maxillary.

The *cartilaginous framework* consists of five pieces, the two upper and the two lower lateral cartilages and the cartilage of the septum.

The *upper lateral cartilages* are situated below the free margin of the nasal bones; each cartilage is flattened and triangular in shape. Its anterior margin is thicker than the posterior, and connected with the fibro-cartilage of the septum. Its posterior margin is attached to the nasal process of the superior maxillary and nasal bones. Its inferior margin is connected by fibrous tissue with the lower lateral cartilage: one surface is turned outward, the other inward toward the nasal cavity.

The *lower lateral cartilages* are two thin, flexible plates situated immediately below the preceding, and bent upon themselves in such a manner as to form the inner and outer walls of each orifice of the nostril. The portion which forms the

inner wall, thicker than the rest, is loosely connected with the same part of the opposite cartilage, and forms a small part of the *columna*. Its inferior border, free, rounded, and projecting, forms, with the thickened integument and subjacent tissue and the corresponding parts of the opposite side, the tip of the nose. The part which forms the outer wall is curved to correspond with the ala of the nose; it is oval and flattened, narrow behind, where it is connected with the nasal process of the superior maxilla by a tough fibrous membrane, in which are found three or four small cartilaginous plates (*sesamoid cartilages*), *cartilagineæ minores*. Above, it is connected

FIG. 481.—Bones and cartilages of septum of nose. Right side.

part of the cartilage of the septum; below, it is separated from the margin of the nostril by dense cellular tissue; and in front, it forms, with its fellow, the lobe of the nose.

The *cartilage of the septum* is somewhat quadrilateral in form, thicker at its margins than at its centre, and completes the separation between the nasal fossæ in front. Its anterior margin, thickest above, is connected from above downward with the nasal bones, the anterior margin of the two upper lateral cartilages, and the inner portion of the two lower lateral cartilages. Its posterior margin is connected with the perpendicular lamella of the ethmoid, its inferior margin with the vomer and the palate processes of the superior maxillary bones.

These various cartilages are connected to each other and to the bones by a

tough fibrous membrane, which allows the utmost facility of movement between them.

The *muscles of the nose* are situated immediately beneath the integument: they are (on each side) the *Pyramidalis nasi*, the *Levator labii superioris alæque nasi*, the *Dilatator naris*, anterior and posterior, the *Compressor nasi*, the *Compressor narium minor*, and the *Depressor alæ nasi*. They have been described above (page 401).

The *integument* covering the dorsum and sides of the nose is thin, and loosely connected with the subjacent parts, but where it forms the tip or lobe and the alæ of the nose it is thicker and more firmly adherent. It is furnished with a large number of sebaceous follicles, the orifices of which are usually very distinct.

The *mucous membrane* lining the interior of the nose is continuous with the skin externally and with that which lines the nasal fossæ within.

The *arteries of the nose* are the *lateralis nasi* from the facial, and the inferior artery of the septum from the superior coronary, which supply the alæ and septum, the sides and dorsum being supplied from the nasal branch of the ophthalmic and the infra-orbital.

The *veins of the nose* terminate in the facial and ophthalmic.

The *nerves of the nose* are branches from the facial, infra-orbital, and infra-trochlear, and a filament from the nasal branch of the ophthalmic.

Nasal Fossæ.

The nasal fossæ are two irregular cavities situated in the middle of the face and extending from before backward. They open in front by the two anterior

FIG. 485.—Transverse vertical section of the nasal fossæ. (Henle.)

nares, and terminate in the pharynx, behind, by the posterior nares. The *anterior nares* are somewhat pear-shaped apertures, each measuring about one inch vertically and half an inch transversely at their widest part. The *posterior nares* are two oval openings situated at the upper part of the anterior wall of the pharynx. They are smaller in the body than in the skeleton, because narrowed by the mucous membrane. Each opening measures an inch in the vertical and half an inch in the transverse direction in a well-developed adult skull.

The *mucous membrane* lining the nasal fossæ is called the *pituitary*, from the nature of its secretion; or *Schneiderian*, from Schneider, the first anatomist who showed that the secretion proceeded from the mucous membrane, and not, as was formerly imagined, from the brain. It is intimately adherent to the periosteum or perichondrium, over which it lies. It is continuous externally with the skin through the anterior nares, and with the mucous membrane of the pharynx through the posterior nares. From the nasal fossæ its continuity may be traced with the conjunctiva through the nasal duct and lachrymal canals; with the lining membrane of the tympanum and mastoid cells through the Eustachian tube; and with the frontal, ethmoidal, and sphenoidal sinuses, and the antrum of Highmore through the several openings in the meatuses. The mucous membrane is thickest and most vascular over the turbinated bones. It is also thick over the septum, but in the intervals between the spongy bones and on the floor of the nasal fossæ it is very thin. Where it lines the various sinuses and the antrum of Highmore it is thin and pale.

Owing to the great thickness of this membrane, the nasal fossæ are much narrower, and the turbinated bones, especially the lower ones, appear larger and more prominent than in the skeleton. From the same circumstance also the various apertures communicating with the meatuses are either narrowed or completely closed.

In the superior meatus the aperture of communication with the posterior ethmoidal cells is considerably diminished in size, and the sphenopalatine foramen completely covered in.

In the middle meatus the opening of the infundibulum is partially hidden by a projecting fold of mucous membrane, and the orifice of the antrum is contracted to a small circular aperture, much narrower than in the skeleton.

In the inferior meatus the orifice of the nasal duct is partially hidden by either a single or double valvular mucous fold, and the anterior palatine canal either completely closed in or a tubular *cul-de-sac* of mucous membrane is continued a short distance into it. This *cul-de-sac* is termed the *organ of Jacobson*, and is present in all mammals as well as man. In the former it consists of a bilateral tube, situated in the nasal septum and supported by hyaline cartilage, the *cartilage of Jacobson*.

In the roof the opening leading to the sphenoidal sinus is narrowed, and the apertures in the cribriform plate of the ethmoid completely closed in.

Structure of the Mucous Membrane.—The epithelium covering the mucous membrane differs in its character according to the functions of the part of the nose in which it is found. Near the orifice of the nostril, the *vestibule*, where common sensation is chiefly or alone required, the epithelium is of the ordinary pavement or scaly variety. In the rest of the cavity, below the distribution of the olfactory nerves—*i.e.* in the respiratory portion of the nasal cavity—the epithelium is columnar and ciliated. This is the case also in the meatuses of the nose. In this region, beneath the epithelium and its basement membrane, is a fibrous layer infiltrated with lymph-corpuscles, so as to form in many parts a diffuse adenoid tissue, and beneath this a nearly continuous layer of smaller and larger glands, some mucous and some serous, the ducts of which open upon the surface. In the olfactory region—*i.e.* the region in which the terminal filaments from the olfactory nerves are distributed (see page 755)—the epithelial cells are columnar and, for the most part, non-ciliated: their free surface presents a sharp outline, and their deep extremity is prolonged into a process which runs inward, branching to communicate with similar processes from neighboring cells, so as to form a network in the deep part of the mucous membrane. Lying between them are cells (termed by Max Schultze, *olfactory cells*), which consist of a nucleated body and two processes, of which one runs outward between the columnar epithelial cells and projects on the surface of the mucous membrane; the other (the deep) process runs inward, is frequently beaded like a nerve-fibre, and is believed by most observers to be in connection with one of the terminal filaments of the olfactory nerve. Amongst

the branched ends of the columnar cells there is a deep layer of epithelial cells of a conical shape, their broad end resting on the basement membrane, and their tapering extremity projecting between the other cells. Beneath the epithelium, extending through the thickness of the mucous membrane, is a layer of glands, the *glands of Bowman*, identical in structure with serous glands.

The mucous membrane is pigmented in the olfactory, but not in the other regions, being of a light yellow color, at least in the white races.¹

The *arteries of the nasal fossæ* are the anterior and posterior ethmoidal, from the ophthalmic, which supply the ethmoidal cells, frontal sinuses, and roof of the nose; a minute twig from the small meningeal; the sphenopalatine, from the internal maxillary, which supplies the mucous membrane covering the spongy bones, the meatuses, and septum; the inferior artery of the septum from the superior coronary of the facial; and the alveolar branch of the internal maxillary, which supplies the lining membrane of the antrum. The ramifications of these vessels form a close, plexiform network beneath and in the substance of the mucous membrane.

The *veins of the nasal fossæ* form a close network beneath the mucous membrane. They pass, some with the veins accompanying the sphenopalatine artery, through the sphenopalatine foramen, and others through the alveolar branch, to join the facial vein; some accompany the ethmoidal arteries and terminate in the ophthalmic vein; and, lastly, a few communicate with the veins in the interior of the skull through the foramina in the cribriform plate of the ethmoid bone and the foramen cæcum.

The *nerves* are—the olfactory, the nasal branch of the ophthalmic, filaments from the anterior dental branch of the superior maxillary, the Vidian, naso-palatine, descending anterior palatine, and nasal branches of Meckel's ganglion.

The *olfactory*, the special nerve of the sense of smell, is distributed over the upper third of the septum and over the surface of the superior and middle spongy bones.

The *nasal branch of the ophthalmic* distributes filaments to the fore part of the septum and outer wall of the nasal fossæ.

Filaments from the anterior dental branch of the superior maxillary supply the inferior meatus and inferior turbinated bone.

The *Vidian nerve* supplies the upper and back part of the septum and superior spongy bone, and the *upper anterior nasal branches* from the sphenopalatine ganglion have a similar distribution.

The *naso-palatine nerve* supplies the middle of the septum.

The *larger or anterior palatine nerve* supplies the middle and lower spongy bones.

Surgical Anatomy.—Instances of congenital deformity of the nose are occasionally met with, such as complete absence of the nose, an aperture only being present, or perfect development on one side, and suppression or malformation on the other; or there may be imperfect apposition of the nasal bones, so that the nose presents a median cleft or furrow. Deformities which have been acquired are much more common, such as flattening of the nose, the result of

FIG. 486.—Nerves of septum of nose. Right side.

¹ An interesting speculation has been suggested by Dr. W. Ogle, (*Med. Chir. Trans.*, vol. liii. p. 277) as to the possible connection between the presence and abundance of this pigment and the perfection of the sense of smell.

syphilitic necrosis, or imperfect development of the nasal bones in cases of congenital syphilis, or a lateral deviation of the nose may result from fracture.

The skin over the ala and tip of the nose is thick and closely adherent to subjacent parts. Inflammation of this part is therefore very painful, on account of the tension. It is largely supplied with blood, and the circulation here being terminal, vascular engorgement is liable to occur, especially in women at the menopause and in both sexes from disorders of digestion, exposure to cold, etc. The skin of the nose also contains a large number of sebaceous follicles, and these, as the result of intemperance, are apt to become affected and the nose reddened, congested, and irregularly swollen. To this the term "grog-blossom" is popularly applied. In some of these cases there is enormous hypertrophy of the skin and subcutaneous tissues, producing pendulous masses, termed *lipomata nasi*. Epithelioma and rodent ulcer may attack the nose, the latter being the more common of the two. Lupus and syphilitic ulceration frequently attack the nose, and may destroy the whole of the cartilaginous portion. In fact, lupus vulgaris begins more frequently on the ala of the nose than in any other situation.

Cases of congenital occlusion of one or both nostrils, or adhesion between the ala and septum may occur, and may require immediate operation, since the obstruction much interferes with sucking. Bony closure of the posterior nares may also occur.

To examine the nasal cavities, the head should be thrown back and the nose drawn upward, the parts being dilated by some form of speculum. It can also be examined with the little finger or a probe, and in this way foreign bodies detected. A still more extensive examination can be made by Rouge's operation, which was introduced for the cure of *ozæna* by the removal of any dead bone which may be present in this disease. The whole framework of the nose is lifted up by an incision made inside the mouth, through the junction of the upper lip with the bone; the septum nasi and the lateral cartilages are divided with strong scissors till the anterior nares are completely exposed. The posterior nares can be explored by reflected light from the mouth, by which the posterior nares can be illuminated. The examination is very difficult to carry out, and, as a rule, sufficient information regarding the presence of foreign bodies or tumors in the naso-pharynx can be obtained by the introduction of the finger behind the soft palate through the mouth. The septum of the nose may be displaced or deviate from the middle line: this may be the result of an injury or from some congenital defect in its development. Sometimes the deviation may be so great that the septum may come in contact with the outer wall of the nasal fossæ, and may even become adherent to it, thus producing complete obstruction. Perforation of the septum is not an uncommon affection, and may arise from several causes: syphilitic or tubercular ulceration, blood-tumor or abscess of the septum, and especially in workmen exposed to the vapor of bichromate of potash, from the irritating and corrosive action of the fumes. When small, the perforation may cause a peculiar whistling sound during respiration. When large, it may lead to the falling in of the bridge of the nose.

Epistaxis is a very common affection in children. It is rarely of much consequence, and will almost always subside, but in the more violent hæmorrhages of later life it may be necessary to plug the posterior nares. In performing this operation it is desirable to remember the size of the posterior nares. A ready method of regulating the size of the plug to fit the opening is to make it of the same size as the terminal phalanx of the thumb of the patient to be operated on.

Nasal polypus is a very common disease, and presents itself in three forms: the gelatinous, the fibrous, and the malignant. The first is by far the most common. It grows from the mucous membrane of the outer wall of the nasal fossa, where there is an abundant layer of highly vascular submucous tissue; rarely from the septum, where the mucous membrane is closely adherent to the cartilage and bone, without the intervention of much, if any, submucous tissue. Their most common seat is probably the middle turbinated bone. The fibrous polypus generally grows from the base of the skull behind the posterior nares or from the roof of the nasal fossæ. The malignant polypi, both sarcomatous or carcinomatous, may arise in the nasal cavities and the naso-pharynx; or they may originate in the antrum, and protrude through its inner wall into the nasal fossa.

Rhinoliths, or nose-stones, may sometimes be found in the nasal cavities, from the formation of phosphate of lime upon either a foreign body or a piece of inspissated secretion.

THE EYE.

The eyeball is contained in the cavity of the orbit. In this situation it is securely protected from injury, whilst its position is such as to ensure the most extensive range of sight. It is acted upon by numerous muscles, by which it is capable of being directed to any part; it is supplied by vessels and nerves, and is additionally protected in front by several appendages, such as the eyebrow, eyelids, etc.

The eyeball is imbedded in the fat of the orbit, but is surrounded by a thin membranous sac, the *capsule of Tenon*, which isolates it, so as to allow of free movement.

The *capsule of Tenon* (*tunica vaginalis oculi*) may be regarded as a distinct

serous membrane, consisting of a parietal and visceral layer. The latter invests the posterior part of the globe from the ciliary margin of the cornea backward to the entrance of the optic nerve, and is connected to it by very delicate connective tissue: the former (parietal) lines the hollow in the fat in which the eyeball is imbedded. Both layers are lined on their free surfaces by endothelial cells. The cavity between them is continuous with the spaces between the different layers of the sheath of the optic nerve—that is to say, with the *subarachnoidean* between the pia-matral and the arachnoid sheath, and the *subdural* between the arachnoid and dural sheath—and into it empty the lymphatic vessels of the sclerotic. The capsule is pierced by the muscles of the eyeball near their insertion, and sends tubular prolongations on them, which become continuous with the sheath of the muscles. From the outer surface of these sheaths expansions, consisting of elastic fibres and muscle-cells, are given off to the margin of the orbit, which serve to limit the degree of contraction of the muscles.¹

The eyeball is composed of segments of two spheres of different sizes. The anterior segment is one of a small sphere, and forms about one-sixth of the eyeball. It is more prominent than the posterior segment, which is one of a much larger sphere, and forms about five-sixths of the globe. The segment of the larger sphere is opaque, and formed by the sclerotic, the tunic of protection to the eyeball; the smaller sphere is transparent, and formed by the cornea. The axes of the eyeballs are nearly parallel, and do not correspond to the axes of the orbits, which are directed outward. The optic nerves follow the direction of the axes of the orbits, and are therefore not parallel; they enter the eyeball a little to their inner or nasal side. The eyeball measures rather more in its transverse than in its antero-posterior and vertical diameters, the former amounting to about an inch, the latter to about nine-tenths of an inch.

The eyeball is composed of several investing tunics, and of fluid and solid refracting media, called *humors*.

The tunics are three in number:

1. Sclerotic and Cornea.
2. Choroid, Iris, and Ciliary Processes.
3. Retina.

The refracting media, or humors, are also three:

Aqueous.	Crystalline (lens) and Capsule.	Vitreous.
----------	---------------------------------	-----------

The sclerotic and cornea form the external tunic of the eyeball; they are essentially fibrous in structure, the sclerotic being opaque, and forming the posterior five-sixths of the globe; the cornea, which forms the remaining sixth, being transparent.

The **Sclerotic** (*σκληρός*, hard) (Fig. 487) has received its name from its extreme density and hardness; it is a firm, unyielding, fibrous membrane, serving to maintain the form of the globe. It is much thicker behind than in front. Its *external surface* is of a white color, quite smooth, except at the points where the Recti and Obliqui muscles are inserted into it, and covered, for part of its extent, by the conjunctival membrane; hence the whiteness and brilliancy of the front of the eyeball. Its *inner surface* is stained of a brown color, marked by grooves, in which are lodged the ciliary nerves, and connected by an exceedingly fine cellular tissue (*lamina fusca*) with the outer surface of the choroid. Behind, it is pierced by the optic nerve a little to its inner or nasal side, and is continuous with the fibrous sheath of the nerve, which is derived from the dura mater. At the point where the optic nerve passes through the sclerotic this membrane forms a thin cribriform lamina (the *lamina cribrosa*); the minute orifices in this layer serve for the transmission of the nervous filaments, and the fibrous septa dividing them from one another are continuous with the membranous processes which separate the bundles of nerve-fibres. One of these openings, larger than the rest, occupies

¹ See a paper by Mr. C. B. Lockwood (*Journal of Anatomy and Physiology*, vol. xx., part i. p. 1).

the centre of the lamella; it is called the *porus opticus*, and transmits the *arteria centralis retinae* to the interior of the eyeball. Around the cribriform lamella are numerous small apertures for the transmission of the ciliary vessels and nerves. In front the sclerotic is continuous with the cornea by direct continuity of tissue, but the opaque sclerotic overlaps the cornea rather more on its outer than on its inner surface.

Structure.—The sclerotic is formed of white fibrous tissue intermixed with fine elastic fibres, and of flattened connective-tissue corpuscles, some of which are pigmented, contained in cell-spaces between the fibres. These fibres are aggregated into bundles which are arranged chiefly in a longitudinal direction. It yields gelatin on boiling. Its vessels are not numerous, the capillaries being of small size, uniting at long and wide intervals. The existence of nerves in it is doubtful.

FIG. 487.—A horizontal section of the eyeball. (Allen.)

The **Cornea** is the projecting transparent part of the external tunic of the eyeball, and forms the anterior sixth of the globe. It is almost circular in shape, occasionally a little broader in the transverse than in the vertical direction. It is convex anteriorly, and projects forward from the sclerotic in the same manner that a watch-glass does from its case. Its degree of curvature varies in different individuals, and in the same individual at different periods of life, it being more prominent in youth than in advanced life, when it becomes flattened. The cornea is dense and of uniform thickness throughout; its posterior surface is perfectly circular in outline, and exceeds the anterior surface slightly in extent, from the latter being overlapped by the sclerotic.

Structure.—The cornea consists of four layers—namely, (1) several strata of epithelial cells, continuous with those of the conjunctiva; (2) a thick central fibrous structure, the *cornea proper*; (3) a homogeneous elastic lamina; and (4) a single layer of epithelial cells, forming part of the lining membrane of the anterior chamber of the eyeball. The name of *membrane of Descemet* or *Demours* is given to this posterior elastic lamina and its endothelial coating.

The *conjunctival epithelium*, which covers the front of the cornea proper, consists of several strata of epithelial cells. The lowermost cells are columnar: then follow two or three layers of polyhedral cells, some of which present ridges and furrows similar to those found in the cuticle. Lastly, there are three or four layers of scaly epithelium with flattened nuclei.

The *proper substance of the cornea* is fibrous, tough, unyielding, perfectly transparent, and continuous with the sclerotic, with which it is identical in structure. It is composed of about sixty flattened lamellæ, superimposed one on another. These lamellæ are made up of bundles of fibrous connective tissue, the fibres of which are directly continuous with the fibres of the sclerotic. The fibres of each lamella are for the most part parallel with each other; those of alternating lamellæ at right angles to each other. Fibres, however, frequently pass from one lamella to the next.

The lamellæ are connected with each other by an interstitial cement-substance, in which are spaces, the *corneal spaces*. The spaces are stellate in shape, and have numerous offsets by which they communicate with other spaces. Each space contains a cell, the *corneal corpuscle*, which resembles in form the space in which it is contained, but does not entirely fill it.

Immediately beneath the conjunctival epithelium the cornea proper presents certain characteristic differences, which have led some anatomists to regard it as a distinct membrane, and it has been named by Bowman the *anterior elastic lamina*. It differs, however, from the true elastic lamina or membrane of Descemet in many essential particulars, presenting evidence of fibrillar structure, and not having the same tendency to curl inward or to undergo fracture when detached from the other layers of the cornea. It consists of extremely closely interwoven fibrils, similar to those found in the rest of the cornea proper, but contains no corneal corpuscles. It seems, therefore, more proper to regard it as a part of the proper tissue of the cornea.¹

The *posterior elastic lamina*, which covers the proper structure of the cornea behind, presents no structure recognizable under the microscope. It consists of a hard, elastic, and perfectly transparent homogeneous membrane, of extreme thinness, which is not rendered opaque by either water, alcohol, or acids. It is very brittle, but its most remarkable property is its extreme elasticity, and the tendency which it presents to curl up or roll upon itself, with the attached surface innermost, when separate from the proper substance of the cornea. Its use appears to be (as suggested by Dr. Jacob) "to preserve the requisite permanent correct curvature of the flaccid cornea proper."

At the margin of the cornea this posterior elastic membrane breaks up into fibres to form a reticular structure at the outer angle of the anterior chamber, the intervals between the fibres forming small cavernous spaces, the *spaces of Fontana*. These little recesses communicate with a somewhat larger space in the substance of the sclerotic close to its junction with the cornea. This is the *canal of Schlemm*, or *sinus circularis iridis*, and, according to some authors, is a lymph-canal, but according to others is a venous sinus. Some of the fibres of this reticulated structure are continued into the front of the iris, forming the *ligamentum pectinatum iridis*, while others are connected with the fore part of the sclerotic and choroid.

The *endothelial lining of the aqueous chamber* covers the posterior surface of the posterior elastic lamina. It consists of a single layer of polygonal flattened transparent nucleated cells, similar to those found lining other serous cavities.

Arteries and Nerves.—The cornea is a non-vascular structure, the capillary vessels terminating in loops at its circumference. Lymphatic vessels have not as yet been demonstrated in it, but are represented by the channels in which the bundles of nerves run; these are lined by an endothelium and are continuous with the cell-spaces. The nerves are numerous, twenty-four to thirty-six in

¹ This layer has been called by Reichert the "anterior limiting layer"—a name which appears more applicable to it than that of "anterior elastic lamina."

number (Kölliker), forty to forty-five (Waldeyer and Sümmich); they are derived from the ciliary nerves and enter the laminated tissue of the cornea. They ramify throughout its substance in a delicate network, and their terminal filaments form a firm and closer plexus on the surface of the cornea proper beneath the epithelium. This is termed the *subepithelial plexus*, and from it fibrils are given off which ramify between the epithelial cells, forming a network which is termed the *intra-epithelial plexus*.

Dissection.—In order to separate the sclerotic and cornea, so as to expose the second tunic, the eyeball should be immersed in a small vessel of water and held between the finger and thumb. The sclerotic is then carefully incised, in the equator of the globe, till the choroid is exposed. One blade of a pair of probe-pointed scissors is now introduced through the opening thus made, and the sclerotic divided around its entire circumference, and removed in separate portions. The front segment being then drawn forward, the handle of the scalpel should be pressed gently against it at its connection with the iris, and, these being separated, a quantity of perfectly transparent fluid will escape; this is the aqueous humor. In the course of the dissection the ciliary nerves may be seen lying in the loose cellular tissue between the choroid and sclerotic or contained in delicate grooves on the inner surface of the latter membrane.

Second Tunic.—This is formed by the choroid behind, the iris and ciliary processes in front, and by the Ciliary muscle, opposite the junction of the sclerotic and cornea.

FIG. 188.—The choroid and iris. (Enlarged.)

The choroid is the vascular and pigmentary tunic of the eyeball investing the posterior five-sixths of the globe, and extending as far forward as the cornea, the ciliary processes being appendages of the choroid developed from its inner surface in front. The iris is the circular muscular septum which hangs vertically behind the cornea, presenting in its centre a large circular aperture, the *pupil*. The Ciliary muscle forms the white ring observed at the point where the choroid and iris join with each other and with the sclerotic and cornea.

The **Choroid** is a thin, highly vascular membrane, of a dark brown or chocolate color, which invests the posterior five-sixths of the central part of the globe. It is pierced behind by the optic nerve, and extends in front as far forward as the ciliary ligament, where it is connected with the iris, and bends inward, forming on its inner surface a series of folds or platings, the *ciliary processes*. It is thicker

behind than in front. Externally it is connected by a fine cellular web (*membrana fusca*) with the inner surface of the sclerotic. Its inner surface is smooth and lies in contact with the retina.

Structure.—The choroid consists mainly of a dense capillary plexus and of small arteries and veins, carrying the blood to and returning it from this plexus. On its external surface—*i. e.* the surface next the sclerotic—is a thin membrane of fine elastic fibres arranged in lamellæ, which are covered with endothelium and form spaces, which communicate by perforations in the sclerotic, through which the vessels and nerves enter, with the capsule of Tenon. This layer is named the *lamina suprachoroidæ*, and is continuous with the lamina fusca of the sclerotic.

Internal to this is the *choroid proper*, and, in consequence of the small arteries and veins being arranged on the outer surface of the capillary network, it is customary to describe this as consisting of two layers, the outermost composed of small arteries and veins, with pigment-cells interspersed between them, and the

FIG. 489.—The veins of the choroid. (Enlarged.)

inner consisting of a capillary plexus. The *external layer* consists, in part, of the larger branches of the short ciliary arteries, which run forward between the veins before they bend inward to terminate in the capillaries; but is formed principally of veins, which are named, from their arrangement, *venæ vorticosæ*. They converge to four or five equidistant trunks, which pierce the sclerotic midway between the margin of the cornea and the entrance of the optic nerve. Interspersed between the vessels are lodged dark star-shaped pigment-cells, the fibrous offsets from which, communicating with similar branchings from neighboring cells, form a delicate network or stroma, which toward the inner surface of the choroid loses its pigmentary character. The *internal layer* consists of an exceedingly fine capillary plexus, formed by the short ciliary vessels, and is known as the *tunica Ruysschiana*. The network is close, and finer at the hinder part of the choroid than in front. About half an inch behind the cornea its meshes become larger, and are continuous with those of the ciliary processes. On the inner surface of this tunic is a very thin, structureless—or, according to Kölliker, faintly fibrous—membrane, called the *lamina vitrea*: it is closely connected with the stroma of the choroid, and separates it from the pigmentary layer of the retina.

The ciliary processes should now be examined. They may be exposed, either by detaching the iris from its connection with the Ciliary muscle, or by making a transverse section of the globe and examining them from behind.

The *ciliary processes* are formed by the plaiting and folding inward of the various layers of the choroid (*i. e.* the choroid proper and the lamina vitrea) at its anterior margin, and are received between corresponding foldings of the suspensory

ligament of the lens, thus establishing a connection between the choroid and inner tunic of the eye. They are arranged in a circle, and form a sort of plaited frill behind the iris round the margin of the lens. They vary between sixty and eighty in number, lie side by side, and may be divided into large and small; the latter, consisting of about one-third of the entire number, are situated in the spaces between the former, but without regular alternation. The larger processes are each about one-tenth of an inch in length, and are attached by their periphery to the Ciliary muscle, and are continuous with the layers of the choroid: the opposite margin is free, and rests upon the circumference of the lens. Their anterior surface is turned toward the back of the iris, with the circumference of which they are continuous. The posterior surface is closely connected with the suspensory ligament of the lens.

Structure.—The ciliary processes are similar in structure to the choroid, but the vessels are larger, and have chiefly a longitudinal direction. They are covered

FIG. 490.—The arteries of the choroid and iris. The sclerotic has been mostly removed. (Enlarged.)

on their inner surface with a layer of black pigment-cells continuous with the cells of the pigmentary layer of the retina, and in their stroma are also other, stellate, pigment-cells, which, however, are not so numerous as in the choroid itself, and toward the free extremities of the folds are devoid of pigment.

The **Iris** (*iris*, a rainbow) has received its name from its various colors in different individuals. It is a thin, circular-shaped, contractile curtain, suspended in the aqueous humor behind the cornea and in front of the lens, being perforated a little to the nasal side of its centre by a circular aperture, the *pupil*, for the transmission of light. By its circumference it is intimately connected with the choroid; externally to this is the Ciliary muscle, by which it is connected to the sclerotic and cornea; its inner edge forms the margin of the pupil; its surfaces are flattened, and look forward and backward, the anterior surface toward the cornea, the posterior toward the ciliary processes and lens. The circumference of the iris is connected to the cornea by a reticular structure denominated the *ligamentum pectinatum iridis*. The anterior surface of the iris is variously colored in different individuals, and marked by lines which converge toward the pupil. The posterior surface is of a deep purple tint, from being covered by dark pigment; it is hence named *uvea*, from its resemblance in color to a ripe grape.

Structure.—The iris is composed of the following structures:

1. In front is a layer of polyhedral cells on a delicate hyaline basement membrane. This layer is continuous with the epithelial layer of the membrane of Descemet, and in men with dark-colored irides the cells contain pigment-granules.

2. *Stroma.*—The stroma consists of fibres and cells. The former are made up

of fine delicate bundles of fibrous tissue, of which some few fibres have a circular direction at the circumference of the iris, but the chief mass consists of fibres radiating toward the pupil. They form, by their interlacement, a delicate mesh, in which the vessels and nerves are contained. Interspersed between the bundles of connective tissue are numerous branched cells with fine processes. Many of them in dark eyes contain pigment-granules, but in blue eyes and the pink eyes of albinos they are unpigmented.

3. The *muscular fibre* is involuntary, and consists of circular and radiating fibres. The *circular fibres* (sphincter of the pupil) surround the margin of the pupil on the posterior surface of the iris, like a sphincter, forming a narrow band

FIG. 491.—Section of the eye, showing the relations of the cornea, sclerotic, and iris, together with the ciliary muscle and the cavernous spaces near the angle of the anterior chamber. (Waldeyer.)

about one-thirtieth of an inch in width, those near the free margin being closely aggregated; those more external somewhat separated, and forming less complete circles. The *radiating fibres* (dilator of the pupil) converge from the circumference toward the centre, and blend with the circular fibres near the margin of the pupil.

4. *Pigment*.—The situation of the pigment-cells differs in different irides. In the various shades of blue eyes the only pigment-cells are several layers of small round or polyhedral cells filled with dark pigment, situated on the posterior surface of the iris and continuous with the pigmentary lining of the ciliary processes. The color of the eye in these individuals is due to this coloring matter showing more or less through the texture of the iris. In the albino even this pigment is absent. In the gray, brown, and black eye there are, as mentioned above, pigment-granules to be found in the cells of the stroma and in the epithelial layer on the front of the iris, to which the color of the eye is due.

The *arteries of the iris* are derived from the long and anterior ciliary and from the vessels of the ciliary processes (see page 572).

The *nerves of the iris* are derived from the ciliary branches of the lenticular ganglion and the long ciliary from the nasal branch of the ophthalmic division of the fifth. After reaching the iris in the manner described above (page 763) they form a plexus around the attached margin of the iris; from this are derived non-

medullated fibres which terminate in the circular and radiating muscular fibres. Their exact mode of termination has not been ascertained. Other fibres from the plexus terminate in a network on the anterior surface of the iris. The fibres derived from the motor root of the lenticular ganglion (third nerve) supply the circular fibres, while those derived from the sympathetic supply the radiating fibres.

Membrana Pupillaris.—In the fœtus the pupil is closed by a delicate transparent vascular membrane, the *membrana pupillaris*, which divides the space into which the iris is suspended into two distinct chambers. This membrane contains numerous minute vessels, continued from the margin of the iris to those on the front part of the capsule of the lens. These vessels have a looped arrangement, and converge toward each other without anastomosing. Between the seventh and eighth months the membrane begins to disappear, by its gradual absorption from the centre toward the circumference, and at birth only a few fragments remain. It is said sometimes to remain permanent and produce blindness.

The *Ciliary muscle* (Bowman) consists of unstriped fibres: it forms a grayish, semitransparent, circular band, about one-eighth of an inch broad, on the outer surface of the fore part of the choroid. It is thickest in front, and gradually becomes thinner behind. It consists of two sets of fibres, radiating and circular. The former, much the more numerous, arise at the point of junction of the cornea and sclerotic, and, passing backward, are attached to the choroid opposite to the ciliary processes. One bundle, according to Waldeyer, is continued backward to be inserted into the sclerotic. The circular fibres are internal to the radiating ones, and to some extent unconnected with them, and have a circular course around the attachment of the iris. They are sometimes called the "ring muscle" of Müller, and were formerly described as the ciliary ligament. The Ciliary muscle is admitted to be the chief agent in accommodation—*i. e.* in adjusting the eye to the vision of near objects. Mr. Bowman believed that this was effected by its compressing the vitreous body, and so causing the lens to advance; but the view which now prevails is that the contraction of the muscle, by drawing on the ciliary processes, relaxes the suspensory ligament of the lens, thus allowing the anterior surface of the lens to become more convex. The pupil is at the same time slightly contracted.¹

The *Retina* is a delicate nervous membrane upon the surface of which the images of external objects are received. Its outer surface is in contact with the choroid, the inner surface with the vitreous body. Behind it is continuous with the optic nerve; it gradually diminishes in thickness from behind forward, and in front extends nearly as far forward as the Ciliary muscle, where it terminates by a jagged margin, the *ora serrata*. It is soft, and semitransparent in the fresh state, but soon becomes clouded, opaque, and of a pinkish tint. Exactly in the centre of the posterior part of the retina, and at a point corresponding to the axis of the eye, in which the sense of vision is most perfect, is a round, elevated, yellowish spot, called, after its discoverer, the *yellow spot* or *limbus luteus* (*macula lutea*) of Sömmerring, having a central depression at its summit, the *fovea centralis*. The retina in the situation of the fovea centralis is exceedingly thin: so much so that the dark color of the choroid is distinctly seen through it; so that it presents more the appearance of a foramen, and hence the name "foramen of Sömmerring" at first given to it. It exists only in man, the quadrumana, and some saurian reptiles. About one-tenth of an inch to the inner side of the yellow spot is the point of entrance of the optic nerve (*porus opticus*); here the nervous substance is slightly raised so as to form an eminence (*colliculus nervi optici*); the arteria centralis retinæ pierces its centre. This is the only part of the surface of the retina from which the power of vision is absent.

Structure.—The retina is an exceedingly complex structure, and, when examined microscopically by means of sections made perpendicularly to its surface,

¹ See explanation and diagram in Power's *Illustrations of Some of the Principal Diseases of the Eye*, p. 590.

is found to consist of ten layers, which are named from within outward as follows :

1. *Membrana limitans interna*.
2. Fibrous layer, consisting of nerve-fibres.
3. Vesicular layer, consisting of nerve-cells.
4. Inner molecular, or granular, layer.
5. Inner nuclear layer.
6. Outer molecular, or granular, layer.
7. Outer nuclear layer.
8. *Membrana limitans externa*.
9. Layer of rods and cones (Jacob's membrane).
10. Pigmentary layer.

1. The *membrana limitans interna* is the most internal layer of the retina, and is in contact with the hyaloid membrane of the vitreous humor. It is derived from the supporting framework of the retina, with which tissue it will be described.

FIG. 492.—The arteria centralis retinae, yellow spot, etc., the anterior half of the eyeball being removed. (Enlarged.)

2. The *fibrous layer* is made up of nerve-fibres, the direct continuation of the fibres of the optic nerve. This nerve therefore passes through all the other layers of the retina, except the one previously mentioned, to reach its destination in the fibrous layer. As the nerve passes through the lamina cribrosa of the sclerotic coat the fibres of which it is composed lay aside their medullary sheaths and are continued onward, through the choroid and retina, as simple axis-cylinders. When these non-medullated fibres reach the internal surface of the retina, they radiate from their point of entrance over the surface of the retina, grouped in bundles, and in many places, according to Michel, arranged in plexuses. The layer is thickest at the optic nerve entrance, and gradually diminishes in thickness toward the ora serrata.

3. The *vesicular layer* consists of a single layer of large ganglion-cells, except in the macula lutea, where there are several layers. The cells are somewhat flask-shaped; their rounded internal margin resting on the preceding layer, and sending off a single process, which is prolonged into the fibrous layer, and is believed to be continuous with a nerve-fibre. From the opposite extremity of the cell one or more thicker processes extend into the inner molecular layer, where they divide dichotomously and become lost in its reticulum, or, according to some, pass through this layer to reach the inner nuclear layer.

4. The *inner molecular layer* consists of a stratum of granular-looking substance, from which circumstance it is sometimes called the "inner granular" layer.

It is made up of a dense reticulum of minute fibrils, intermingled with the fine processes of the ganglion-cells and also processes derived from certain cells contained in the next layer, immediately to be described. No direct connection between these sets of processes has yet been demonstrated, but it is considered probable that they do communicate, and that there is therefore a direct connection between the ganglion-cells of the vesicular layer and the nuclear cells of the inner nuclear layer. Within the reticulum formed by these fibrils minute clear granules, of unknown nature, are imbedded.

5. The *inner nuclear layer* is made up of nuclear bodies, of which there are

FIGS. 493, 494.—Vertical sections of the human retina. FIG. 493, half an inch from the entrance of the optic nerve. FIG. 494, close to the latter. 1. Layer of rods and cones (*columnar layer*), bounded underneath by the *membrana limitans externa*. 2. External nuclear layer. 3. Outer molecular layer. 4. Internal nuclear layer. 5. Inner molecular layer. 6. Layer of the ganglion-cells. 7. Expansion of optic fibres. 8. Sustentacular fibres of Müller. 9. Their attachment to the *membrana limitans interna*.

three different kinds: (1) A large number of oval nuclei, which are commonly regarded as bipolar nerve-cells, and are much more numerous than either of the other kind. They consist of a large oval nuclear body placed vertically to the surface, containing a distinct nucleolus: they are surrounded by a small amount of protoplasm, which is prolonged into two processes: one of these passes inward into the inner molecular layer, is varicose in appearance, and, as stated above, is believed to be continuous with the processes of the ganglion-cells. The other process passes outward into the outer molecular layer, and there bifurcates. According to some observers, the divisions thus formed communicate with the rod- and cone-fibres (Merkel). (2) At the innermost part of this inner nuclear layer is a stratum of cells which are not branched. (3) Some few cells are also found in this layer connected with the fibres of Müller, and will be described with those structures.

6. The *outer molecular layer* is much thinner than the inner molecular layer, but, like it, consists of a dense network of minute fibrils, and presents the same granular appearance. It differs, however, from the inner molecular layer in containing branched stellate cells, the processes of which are extremely fine and exhibit varicosities like nerve-fibrils. They are therefore considered by Schultze to be ganglion-cells.

7. *The Outer Nuclear Layer.*—Like the inner nuclear layer, this layer contains several strata of clear oval nuclear bodies: they are of two kinds, and, on account of their being respectively connected with the rods and cones of Jacob's membrane,

are named rod-granules and cone-granules. The *rod-granules* are much the more numerous, and are placed at different levels throughout the layer. They present a peculiar cross-striped appearance, and have prolonged from either extremity a fine process: the outermost is continuous with a single rod of Jacob's membrane; the innermost passes inward toward the outer molecular layer, and terminates in an enlarged extremity, from which are given off a number of minute fibrils, which enter the outer molecular layer. In its course it presents numerous varicosities.

The *cone-granules*, fewer in number than the rod-granules, are placed close to the *membrana limitans externa*, and are closely connected with the cones of Jacob's membrane. They do not present any cross-striping, but contain a pyriform nucleus, which almost completely fills the cell. From their inner extremity a thick process passes inward to the outer molecular layer, where, like the processes of the rod-cells, it terminates in an enlargement, from which are given off numerous fine fibrils which enter the outer molecular layer.

8. *The Membrana Limitans Externa*.—This layer, like the *membrana limitans interna*, is derived from the fibres of Müller, with which structures it will be described.

9. *Jacob's Membrane (bacillary layer)*.—The elements which compose this layer are of two kinds, *rods* and *cones*, the former being much more numerous than the latter. The *rods* are solid, of nearly uniform size, and arranged perpendicularly to the surface. Each rod consists of two portions, an outer and inner, which are joined together by a cement-substance and are of about equal length. They differ from each other as regards refraction and in their behavior with coloring reagents, the inner portion becoming stained by carmine, iodine, etc., the outer portion remaining unstained. The outer portion of each rod is marked by transverse striæ, and is made up of a number of thin disks superimposed on one another. It also exhibits faint longitudinal markings. The inner portion of each rod at its inner extremity, where it is joined to the processes of the rod-granules, is indistinctly granular; at its outer extremity it presents a fine longitudinal striation, being composed of fine, bright, highly refracting fibrils.

The *cones* are conical or flask-shaped, their broad ends resting upon the *membrana limitans externa*, the narrow pointed extremity being turned to the choroid. Like the rods, they are made up of two portions, outer and inner; the outer portion being a short conical process, which, like the outer segment of the rods, presents transverse striæ. The inner portion resembles the inner portion of the rods in structure, presenting an outer striated and an inner granular appearance, but differs from it in size, being bulged out laterally and presenting a flask shape.

10. *The Pigmentary Layer, or Tapetum Nigrum*.—The most external layer of the retina, formerly regarded as a part of the choroid, consists of a single layer of hexagonal epithelium cells loaded with pigment-granules (Fig. 21). In the eyes of albinos the cells of the pigmentary layer are present, but they contain no coloring matter. In many of the mammals also, as in the horse, and many of the carnivora, there is no pigment in the cells of this layer, and the choroid possesses a beautiful iridescent lustre, which is termed the *tapetum lucidum*.

Connective-tissue Framework of the Retina.—Almost all these layers of the retina are connected together by a sort of supporting connective tissue, which has been named the *fibres of Müller, or radiating fibres*, from which the *membrana limitans interna et externa* are derived. These fibres are found stretched between the two limiting layers, "as columns between a floor and a ceiling," and passing through all the nervous layers except Jacob's membrane. They commence on the inner surface of the retina by a conical base, the edges of the bases of adjoining fibres being united, and thus forming a boundary-line which is the *membrana limitans interna*. As they pass through the various layers they present a roughness on their surface, as if a number of membranous processes had been abruptly broken off. By these they are continuous with the reticulum of the inner and outer molecular layer and with a sponge-like stroma, in which the nuclei of the inner nuclear layers are imbedded. In the inner nuclear layer each fibre of Müller

presents a clear oval nucleus, referred to above, which is sometimes situated at the side of, sometimes altogether within, the fibre. In the outer nuclear layer the fibre breaks up into fine lamellæ, which form a fenestrated or sponge-like tissue, in which the rod- and cone-granules are enclosed, and at the outer border of this layer these lamellæ unite along a definite line, forming the *membrana limitans externa*.

Macula Lutea and Fovea Centralis.—The structure of the retina at the yellow spot presents some modifications. In the macula lutea (1) the nerve-fibres are

FIG. 495.—The layers of the retina (diagrammatic). (After Schultze.)

wanting as a continuous layer; (2) the vesicular layer consists of several strata of cells, instead of a single layer; (3) in Jacob's membrane there are no rods, but only cones, and these are longer and narrower than in other parts; and (4) in the outer nuclear layer there are only cone-fibres, which are very long and arranged in curved lines. At the fovea centralis the only parts which exist are the cones of Jacob's membrane, the outer nuclear layer, the cone-fibres of which are almost horizontal in direction, and an exceedingly thin inner granular layer. The color of the spot seems to imbue all the layers except Jacob's membrane; it is of a rich yellow, deepest toward the centre, and does not appear to consist of pigment-cells, but simply a staining of the constituent parts.

At the *ora serrata* the layers of the retina for the most part terminate abruptly, and the radiating fibres of Müller, covered by the pigmentary layer, can be traced forward, as the *pars ciliaris*, to the iris. The fibres of Müller here present the appearance of columnar epithelial cells arranged in a single stratum.

The *arteria centralis retinae* and its accompanying vein pierce the optic nerve, and enter the globe of the eye through the porus opticus. It immediately divides

into four or five branches, which at first run between the hyaloid membrane and the nervous layer, but they soon enter the latter membrane, and pass forward, dividing dichotomously. From these branches a minute capillary plexus is given off, which does not extend beyond the inner nuclear layer. In the foetus a small vessel passes forward, through the vitreous humor, to the posterior surface of the capsule of the lens.

Humors of the Eye.

The **aqueous humor** completely fills the anterior and posterior chambers of the eyeball. It is small in quantity (scarcely exceeding, according to Petit, four or five grains in weight), has an alkaline reaction, in composition is little more than water, less than one-fiftieth of its weight being solid matter, chiefly chloride of sodium.

The *anterior chamber* is a space bounded in front by the cornea, behind by the front of the iris. The *posterior chamber* was the name formerly given to a space which was believed to exist between the iris in front and the capsule of the lens, its suspensory ligament, and the ciliary processes behind. It is now known that the posterior surface of the iris is in immediate contact with the lens throughout the greater part of its extent. The only space which remains to represent the posterior chamber is a narrow chink between the peripheral part of the iris, the suspensory ligament, and the ciliary processes.

In the adult these two chambers communicate through the pupil; but in the foetus in the seventh month, when the pupil is closed by the *membrana pupillaris*, the two chambers are quite separate.

The Vitreous Body.

The **vitreous body** forms about four-fifths of the entire globe. It fills the cavity of the retina, and is hollowed in front for the reception of the lens and its capsule. It is perfectly transparent, of the consistence of thin jelly, and is composed of an albuminous fluid enclosed in a delicate transparent membrane, the *hyaloid*. This membrane invests the outer surface of the vitreous body; it is intimately connected in front with the suspensory ligament of the lens, and is continued into the back part of the capsule of the lens. It has been supposed, by Hannover, that from its inner surface numerous thin lamellæ are prolonged inward in a radiating manner, forming spaces in which the fluid is contained. In the adult these lamellæ cannot be detected even after careful microscopic examination; but in the foetus a peculiar fibrous texture pervades the mass, the fibres joining at numerous points, and presenting minute nuclear granules at their point of junction. In the centre of the vitreous humor, running from the position of the entrance of the optic nerve on the retina to the posterior surface of the lens, is a canal filled with fluid and lined by a prolongation of the hyaloid membrane. This is the *canal of Stilling*, and is the canal which in the embryonic vitreous humor conveyed the minute artery from the central artery of the retina to the back of the lens. The fluid from the vitreous body resembles nearly pure water; it contains, however, some salts and a little albumen.

The hyaloid membrane encloses the whole of the vitreous humor, except its anterior surface, which is hollowed out for the reception of the lens; it passes from the margin of this surface to the margin of the lens, forming the *suspensory ligament*. It is a delicate structureless membrane, except where it forms the suspensory ligament, where it contains longitudinal elastic fibres. Immediately beneath the hyaloid membrane are found small, granular, nucleated cells which are said to be possessed of amoeboid movements.

In the *foetus* the centre of the vitreous humor presents a tubular canal, through which a minute artery passes along the vitreous body to the capsule of the lens. In the *adult* no vessels penetrate its substance, so that its nutrition must be carried on by the vessels of the retina and ciliary processes situated upon its exterior.

The Crystalline Lens and its Capsule.

The crystalline lens, enclosed in its capsule, is situated immediately behind the pupil, in front of the vitreous body, and surrounded by the ciliary processes, which slightly overlap its margin.

The *capsule of the lens* is a transparent, highly elastic, and brittle membrane which closely surrounds the lens. It rests, behind, in a depression in the fore part of the vitreous body; in front it is in contact with the free border of the iris, this latter receding from it at the circumference, thus forming the posterior chamber of the eye; and it is retained in its position chiefly by the suspensory ligament of the lens. The capsule is much thicker in front than behind, structureless in texture, and when ruptured the edges roll up with the outer surface innermost, like the elastic lamina of the cornea. The anterior surface of the lens is connected to the inner surface of the capsule by a single layer of transparent, polygonal, nucleated cells. At the circumference of the lens these cells undergo a change in form: they become elongated, and Babucin states that he can trace the gradual transition of the cells into proper lens-fibres, with which they are directly continuous. There is no epithelium on the posterior surface.

FIG. 496.—The crystalline lens, hardened and divided. (Enlarged.)

In the fœtus a small branch from the arteria centralis retinae runs forward, as already mentioned, through the vitreous humor to the posterior part of the capsule of the lens, where its branches radiate and form a plexiform network which covers its surface, and they are continuous round the margin of the capsule with the vessels of the pupillary membrane and with those of the iris. In

the adult no vessels enter its substance.

The *lens* is a transparent, double-convex body, the convexity being greater on the posterior than on the anterior surface. It measures about a third of an inch in the transverse diameter, and about one-fourth in the antero-posterior. It consists of concentric layers, of which the external in the fresh state are soft and easily detached; those beneath are firmer, the central ones forming a hardened nucleus. These laminae are best demonstrated by boiling, or immersion in alcohol. The same reagents demonstrate that the lens consists of three triangular segments, the sharp edges of which are directed toward the centre, the bases toward the circumference. The laminae consist of minute parallel fibres which are hexagonal prisms, the edges being dentated, and the dentations fitting accurately into each other; their breadth is about $\frac{1}{5000}$ th of an inch. They run from the sutures or lines of junction of the triangular segments on the one surface to the periphery of the lens, and, curving round its margin, they terminate at the line of junction of the segments on the other. No fibres pass from pole to pole, but they are arranged in such a way that fibres which commence near the pole on the one aspect of the lens—that is to say, near the apex of the triangular segment—terminate near the peripheral extremity of the plane on the other, or near the base of the triangular segment, and *vice versa*. The fibres of the outer layers of the lens each contain a nucleus, which together form a layer (nuclear layer) on the surface of the lens, most distinct toward its circumference. The meridians, or lines of junction of the three segments, are composed of an amorphous granular substance which sometimes becomes opaque, when the lines are seen forming a distinct star on the lens. The lines on one surface do not lie immediately opposite those on the other, but are intermediate.

The changes produced in the lens by age are the following:

In the *fœtus* its form is nearly spherical, its color of a slightly reddish tint, it is not perfectly transparent, and is so soft as to break down readily on the slightest pressure.

In the adult the posterior surface is more convex than the anterior; it is colorless, transparent, and firm in texture.

In old age it becomes flattened on both surfaces, slightly opaque, of an amber tint, and increases in density.

The *suspensory ligament of the lens* is a thin, transparent, membranous structure placed between the vitreous body and the ciliary processes of the choroid; it connects the anterior margin of the vitreous humor with the anterior surface of the lens near its circumference. It assists in retaining the lens in its position. Its outer surface presents a number of folds or plaitings in which the corresponding folds of the ciliary processes are received. These plaitings are arranged round the lens in a radiating form, and are stained by the pigment of the ciliary processes. The suspensory ligament is a part of the hyaloid membrane, which, as described above, is continued forward to the anterior part of the margin of the lens. It is covered on its outer surface by the *pars ciliaris*, or connective-tissue framework of the retina, prolonged forward from the *ora serrata*. That portion of this membrane which intervenes between the ciliary processes and the capsule of the lens forms part of the boundary of the posterior chamber of the eye. The posterior surface of this layer is turned toward the vitreous humor, being separated from it at the circumference of the lens by a space called the canal of Petit.

The *canal of Petit* is about one-tenth of an inch wide. It is bounded in front by the suspensory ligament; behind by the vitreous humor, its base being formed by the capsule of the lens. When inflated with air it is sacculated at intervals, owing to the foldings on its anterior surface.

The *arteries of the globe of the eye* are the short, long, and anterior ciliary arteries and the *arteria centralis retinae*. They have been already described (see page 572).

The *ciliary veins* are seen on the outer surface of the choroid, and are named, from their arrangement, the *venae vorticosae*. They converge to four or five equidistant trunks, which pierce the sclerotic midway between the margin of the cornea and the entrance of the optic nerve. Another set of veins accompany the anterior ciliary arteries and open into the ophthalmic vein.

The *ciliary nerves* are derived from the nasal branch of the ophthalmic and from the ciliary or ophthalmic ganglion.

Surgical Anatomy.—Foreign bodies frequently get into the conjunctival sac and cause great pain, especially if they come in contact with the corneal surface during the movements of the lid and the eye on each other. The conjunctiva is frequently involved in severe injuries of the eyeball, but is seldom ruptured alone; the most common form of injury to the conjunctiva alone is from a burn, either from fire, strong acids, or lime. In these cases union is liable to take place between the eyelid and the eyeball. The conjunctiva is often the seat of inflammation arising from many different causes, and the arrangement of the conjunctival vessels should be remembered as affording a means of diagnosis between this condition and injection of the sclerotic, which is present in inflammations of the deeper structures of the globe. The inflamed conjunctiva is bright red; the vessels are large and tortuous, and greatest at the circumference, shading off toward the corneal margin; they anastomose freely and form a dense network, and they can be emptied or displaced by gentle pressure.

From a surgical point of view the cornea may be regarded as consisting of three layers: (1) of an external epithelial layer, developed from the epiblast, and continuous with the external epithelial covering of the rest of the body, and therefore in its lesions resembling those of the epidermis and superficial layers of the derma; (2) of the cornea proper, derived from the mesoblast, and associated in its diseases with the fibro-vascular structures of the body; and (3) the posterior elastic layer with its endothelium, also derived from the mesoblast and having the characters of a serous membrane, so that inflammation of it resembles inflammation of the other serous and synovial membranes of the body.

The cornea contains no blood-vessels, except at its periphery, where numerous delicate loops, derived from the anterior ciliary arteries, may be demonstrated on the anterior surface of the cornea. The rest of the cornea is nourished by lymph, which gains access to the proper substance of the cornea and the posterior layer through the spaces of Fontana. This lack of a direct blood-supply renders the cornea very apt to inflame in the cachectic and ill-nourished. In cases of granular lids there is a peculiar affection of the cornea, called *pannus*, in which the anterior layers of the cornea become vascularized, and a rich network of blood-vessels may be seen on the cornea; and in interstitial keratitis new vessels extend into the cornea, giving it a pinkish hue, to which the term "salmon patch" is applied. The cornea is richly supplied with

nerves, derived from the ciliary, which enter the cornea through the fore part of the sclerotic and form plexuses in the stroma, terminating between the epithelial cells by free ends or in corpuscles. In cases of glaucoma the ciliary nerves may be pressed upon as they course between the choroid and sclerotic, and the cornea becomes anæsthetic. The sclerotic has very few blood-vessels and nerves. The blood-vessels are derived from the anterior ciliary, and form an open plexus in its substance. As they approach the corneal margin this arrangement is peculiar. Some branches pass through the sclerotic to the ciliary body; others become superficial and lie in the episcleral tissue, and form arches, by anastomosing with each other, some little distance behind the corneal margin. From these arches numerous straight vessels are given off, which run forward to the cornea, forming its marginal plexus. In inflammation of the sclerotic and episcleral tissue these vessels become conspicuous, and form a pinkish zone of straight vessels radiating from the corneal margin, commonly known as the zone of ciliary injection. In inflammation of the iris and ciliary body this zone is present, since the sclerotic speedily becomes involved when these structures are inflamed. But in inflammation of the cornea the sclerotic is seldom much affected, though the cornea and sclerotic are structurally continuous. This would appear to be due to the fact that the nutrition of the cornea is derived from a different source from that of the sclerotic. The sclerotic may be ruptured subcutaneously without any laceration of the conjunctiva, and the rupture usually occurs near the corneal margin, where the tunic is thinnest. It may be complicated with lesions of adjacent parts—laceration of the choroid, retina, iris, or suspensory ligament of the lens—and is then often attended with hæmorrhage into the anterior chamber, which masks the nature of the injury. In some cases the lens has escaped through the rent in the sclerotic, and has been found under the conjunctiva. Wounds of the sclerotic are always dangerous, and are often followed by inflammation, suppuration, and by sympathetic ophthalmia.

The function of the choroid is to provide nutrition for the retina and to convey vessels and nerves to the ciliary body and iris. Inflammation of the choroid is therefore followed by grave disturbance in the nutrition of the retina, and is attended with early interference with vision. In its diseases it bears a considerable analogy to those which affect the skin, and, like it, is one of the places from which melanotic sarcomata may grow. These tumors contain a large amount of pigment in their cells, and grow only from those parts where pigment is naturally present. The choroid may be ruptured without injury to the other tunics, as well as participating in general injuries of the eyeball. In cases of uncomplicated rupture the injury is usually at its posterior part, and is the result of a blow on the front of the eye. It is attended by considerable hæmorrhage, which for a time may obscure vision, but in most cases this is restored as soon as the blood is absorbed.

The iris is the seat of a malformation, termed *coloboma*, which consists in a deficiency or cleft, which in a great number of cases is clearly due to an arrest in development. In these cases it is found at the lower aspect, extending directly downward from the pupil, and the gap frequently extends through the choroid to the entrance of the optic nerve. In some rarer cases the gap is found in other parts of the iris, and is then not associated with any deficiency of the choroid. The iris is abundantly supplied with blood-vessels and nerves, and is therefore very prone to become inflamed. And when inflamed, in consequence of the intimate relationship which exists between the vessels of the iris and choroid this latter tunic is very apt to participate in the inflammation. And, in addition, inflammation of adjacent structures, the cornea and sclerotic, is apt to spread into the iris. The iris is covered with epithelium, and partakes of the character of a serous membrane, and, like these structures, is liable to pour out a plastic exudation when inflamed, and contract adhesions, either to the cornea in front (*synechia anterior*), or to the capsule of the lens behind (*synechia posterior*). In iritis the lens may become involved, and the condition known as secondary cataract may be set up. Tumors occasionally commence in the iris; of these, cysts, which are usually congenital and sarcomatous tumors, are the most common and require removal. Gummata are not unfrequently found in this situation. In some forms of injury of the eyeball, as the impact of a spent shot, the rebound of a twig, or a blow with a whip, the iris may be detached from the ciliary muscle, the amount of detachment varying from the slightest degree to the separation of the whole iris from its ciliary connection.

The retina, with the exception of its pigment-layer and its vessels, is perfectly transparent, so as to be invisible when examined by the ophthalmoscope, so that its diseased conditions are recognized by its loss of transparency. In retinitis, for instance, there is more or less dense and extensive opacity of its structure, and not unfrequently extravasations of blood into its substance. Hæmorrhages may also take place into the retina from rupture of a blood-vessel without inflammation.

The retina may become displaced from effusion of serum between it and the choroid or by blows on the eyeball, or may occur without apparent cause in progressive myopia, and in this case the ophthalmoscope shows an opaque, tremulous cloud. Glioma, a form of sarcoma, and essentially a disease of early life, is occasionally met with in connection with the retina.

The lens has no blood-vessels, nerves, or connective tissue in its structure, and therefore is not subject to those morbid changes to which tissues containing these structures are liable. It does, however, present certain morbid or abnormal conditions of various kinds. Thus, variations in shape, absence of the whole or a part of the lens, and displacements are amongst its congenital defects. Opacities may occur from injury, senile changes, malnutrition, or errors in growth or development. Senile changes may take place in the lens, impairing its elasticity and render-

ing it harder than in youth, so that its curvature can only be altered to a limited extent by the Ciliary muscle. And, finally, the lens may be dislocated or displaced by blows upon the eyeball, and its relations to surrounding structures altered by adhesions or the pressure of new growths.

There are two particular regions of the eye which require special notice: one of these is known as the "filtration area," and the other as the "dangerous area." The *filtration area* is the circumcorneal zone immediately in front of the iris. Here are situated the cavernous spaces of Fontana, which communicate with the canal of Schlemm, through which the chief transudation of fluid from the eye is now believed to take place. The *dangerous area of the eye* is the region in the neighborhood of the ciliary body, and wounds or injuries in this situation are peculiarly dangerous; for inflammation of the ciliary body is liable to spread to many of the other structures of the eye, especially to the iris and choroid, which are intimately connected by nervous and vascular supplies. Moreover, wounds which involve the ciliary region are especially liable to be followed by sympathetic ophthalmia, in which destructive inflammation of one eye is excited by some irritation in the other.

The Appendages of the Eye.

The appendages of the eye (*tutamina oculi*) include the eyebrows, the eyelids, the conjunctiva, and the lachrymal apparatus—viz. the lachrymal gland, the lachrymal sac, and the nasal duct.

The **eyebrows** (*supercilia*) are two arched eminences of integument which surmount the upper circumference of the orbit on each side, and support numerous short, thick hairs, directed obliquely on the surface. In structure the eyebrows consist of thickened integument, connected beneath with the Orbicularis palpebrarum, Corrugator supercilii, and Occipito-frontalis muscles. These muscles serve, by their action on this part, to control to a certain extent the amount of light admitted into the eye.

The **eyelids** (*palpebræ*) are two thin, movable folds placed in front of the eye, protecting it from injury by their closure. The upper lid is the larger and the more movable of the two, and is furnished with a separate elevator muscle, the *Levator palpebræ superioris*. When the eyelids are opened an elliptical space (*fissura palpebrarum*) is left between their margins, the angles of which correspond to the junction of the upper and lower lids, and are called *canthi*.

The *outer canthus* is more acute than the inner, and the lids here lie in close contact with the globe; but the *inner canthus* is prolonged for a short distance inward toward the nose, and the two lids are separated by a triangular space, the *lacus lachrymalis*. At the commencement of the lacus lachrymalis, on the margin of each eyelid, is a small conical elevation, the *lachrymal papilla*, or tubercle, the apex of which is pierced by a small orifice, the *punctum lachrymale*, the commencement of the lachrymal canal.

The *eyelashes* (*cilia*) are attached to the free edges of the eyelids; they are short, thick, curved hairs, arranged in a double or triple row at the margin of the lids: those of the upper lid, more numerous and longer than the lower, curve upward; those of the lower lid curve downward, so that they do not interlace in closing the lids. Near the attachment of the eyelashes are the openings of a number of glands, *glands of Mohl*, arranged in several rows close to the free margin of the lid. They resemble in structure a portion of a sweat-gland, and are regarded as the modified sweat-glands of this region.

Structure of the Eyelids.—The eyelids are composed of the following structures, taken in their order from without inward:

Integument, areolar tissue, fibres of the Orbicularis muscle, tarsal plate (cartilage), and its ligament, Meibomian glands and conjunctiva. The upper lid has, in addition, the aponeurosis of the Levator palpebræ.

The *integument* is extremely thin, and continuous at the margin of the lids with the conjunctiva.

The *subcutaneous areolar tissue* is very lax and delicate, seldom contains any fat, and is extremely liable to serous infiltration.

The *fibres of the Orbicularis muscle*, where they cover the palpebræ, are thin, pale in color, and possess an involuntary action.

The *tarsal plates* (*cartilages*)¹ are two thin elongated plates of dense connective tissue about an inch in length. They are placed one in each lid, contributing to their form and support.

The *superior*, the larger, is of a semilunar form, about one-third of an inch in breadth at the centre, and becoming gradually narrowed at each extremity. Into the anterior surface of this plate the aponeurosis of the Levator palpebræ is attached.

The *inferior tarsal plate*, the smaller, is thinner and of an elliptical form.

The *free* or *ciliary margin* of these plates is thick, and presents a perfectly straight edge. The *attached* or *orbital margin* is connected to the circumference of the orbit by the fibrous membrane of the lids with which it is continuous. The outer angle of each plate is attached to the malar bone by the external palpebral or tarsal ligament. The inner angles of the two plates terminate at the commencement of the lacus lachrymalis, being fixed to the margins of the orbit by the tendo oculi.

The *tarsal ligament*, or *fibrous membrane of the lids*, is a layer of fibrous membrane beneath the Orbicularis, attached marginally to the edge of the orbit, where it becomes continuous with the periosteum, and centrally to the tarsal plate, near its ciliary margin, with the tissue of which it is continuous. It is thickest and densest at the outer part of the orbit. Upon its under surface is a layer of unstriped muscle, which in the upper lid passes from the aponeurosis of the Levator palpebræ muscle to the tarsal plate. This ligament serves to support the eyelids, and retains the tarsal plates in their position.

The *Meibomian glands* (Fig. 497) are situated upon the inner surface of the eyelids between the tarsal plates and conjunctiva, and may be distinctly seen through the mucous membrane on everting the eyelids, presenting the appearance of parallel strings of pearls. They are about thirty in number in the upper eyelid, and somewhat fewer in the lower. They are imbedded in grooves in the inner surface of the tarsal plates, and correspond in length with the breadth of each plate; they are, consequently, longer in the upper than in the lower eyelid. Their ducts open on the free margin of the lids by minute foramina, which correspond in number to the follicles. The peculiar parallel arrangement of these glands, side by side, forms a smooth layer adapted to the surface of the globe, over which they constantly glide. The use of their secretion is to prevent adhesions of the lids.

Structure of the Meibomian Glands.—These glands are a variety of the cutaneous sebaceous glands, each consisting of a single straight tube or follicle, having a cæcal termination, and with numerous small secondary follicles opening into it. The tubes consist of basement membrane, covered by a layer of scaly epithelium; the secondary follicles are lined by a layer of polyhedral cells continuous with the cells of the tube. The remainder of the follicle is filled with large polyhedral cells charged with fat. They are thus identical in structure with the sebaceous glands.

The *conjunctiva* is the mucous membrane of the eye. It lines the inner surface of the eyelids, and is reflected over the fore part of the sclerotic and cornea. In each of these situations its structure presents some peculiarities.

The *palpebral portion of the conjunctiva* is thick, opaque, highly vascular, and covered with numerous papillæ, its deeper parts presenting a considerable amount of lymphoid tissue. At the margin of the lids it becomes continuous with the lining membrane of the ducts of the Meibomian glands, and, through the lachrymal canals, with the lining membrane of the lachrymal sac and nasal duct. At the outer angle of the upper lid it may be traced along the lachrymal ducts into the lachrymal gland, and at the inner angle of the eye it forms a semilunar fold, the *plica semilunaris*. The folds formed by the reflection of the conjunctiva from the lids on to the eye are called the *superior* and *inferior palpebral folds*, the

¹ Recent observations have proved that the so-called "tarsal cartilages" do not contain any cartilage-cells, and that the name is a misnomer.

former being the deeper of the two. Upon the *sclerotic* the conjunctiva is loosely connected to the globe: it becomes thinner, loses its papillary structure, is transparent, and only slightly vascular in health. Upon the *cornea* the conjunctiva consists only of epithelium, constituting the anterior layer of the cornea (conjunctival epithelium) already described (see page 855). *Lymphatics* arise in the conjunctiva in a delicate zone around the cornea, from which the vessels run to the ocular conjunctiva.

At the point of reflection of the conjunctiva from the lid on to the globe of the eye, termed the *fornix conjunctive*, are a number of mucous glands which are much convoluted. They are chiefly found in the upper lid. Other glands, analogous to

FIG. 497.—The Meibomian glands, etc., seen from the inner surface of the eyelids.

lymphoid follicles, and called by Henle *trachoma glands*, are found in the conjunctiva, and, according to Strohmeier, are chiefly situated near the inner canthus of the eye. They were first described by Brush, in his description of Peyer's patches of the small intestines, as "identical structures existing in the under eyelid of the ox."

The nerves in the conjunctiva are numerous and form rich plexuses. According to Krause, they terminate in a peculiar form of tactile corpuscle, which he terms the "terminal bulb."

The *caruncula lachrymalis* is a small, reddish, conical-shaped body, situated at the inner canthus of the eye, and filling up the small triangular space in this situation, the *lacus lachrymalis*. It consists of a cluster of follicles similar in structure to the Meibomian, covered with mucous membrane, and is the source of the whitish secretion which constantly collects at the inner angle of the eye. A few slender hairs are attached to its surface. On the outer side of the caruncula is a slight semilunar fold of mucous membrane, the concavity of which is directed toward the cornea; it is called the *plica semilunaris*. Müller found smooth muscular fibres in this fold, and in some of the domesticated animals a thin plate of cartilage has been discovered. This structure is considered to be the rudiment of the third eyelid in birds, the *membrana nictitans*.

The Lachrymal Apparatus (Fig. 498).

The lachrymal apparatus consists of the lachrymal gland, which secretes the tears, and its excretory ducts, which convey the fluid to the surface of the eye. This fluid is carried away by the lachrymal canals into the lachrymal sac, and along the nasal duct into the cavity of the nose.

The **lachrymal gland** is lodged in a depression at the outer angle of the orbit, on the inner side of the external angular process of the frontal bone. It is of an

oval form, about the size and shape of an almond. Its upper convex surface is in contact with the periosteum of the orbit, to which it is connected by a few fibrous bands. Its under concave surface rests upon the convexity of the eyeball and upon the Superior and External recti muscles. Its vessels and nerves enter its posterior border, whilst its anterior margin is closely adherent to the back part of the upper eyelid, where it is covered to a slight extent by the reflection of the conjunctiva. The fore part of the gland is separated from the rest by a fibrous septum: hence it is sometimes described as a separate lobe, called the *palpebral portion of the gland* (*accessory gland of Rosenmüller*). Its ducts, about seven in number, run obliquely beneath the mucous membrane for a short distance, and, separating from each other, open by a series of minute orifices on the upper and outer half

FIG. 498.—The lacrimal apparatus. Right side.

of the conjunctiva near its reflection on to the globe. These orifices are arranged in a row, so as to disperse the secretion over the surface of the membrane.

Structure of the Lacrimal Gland.—In structure and general appearance the lacrimal resembles the serous salivary glands (page 908). In the recent state the cells are so crowded with granules that their limits can hardly be defined. They contain an oval nucleus, and the cell-protoplasm is finely fibrillated.

The **lacrimal canals** commence at the minute orifices, *puncta lachrymalia*, on the summit of a small conical elevation, the *lacrimal papilla*, seen on the margin of the lids at the outer extremity of the lacus lachrymalis. The *superior canal*, the smaller and shorter of the two, at first ascends, and then bends at an acute angle, and passes inward and downward to the lacrimal sac. The *inferior canal* at first descends, and then, abruptly changing its course, passes almost horizontally inward to the lacrimal sac. These canals are dense and elastic in structure and somewhat dilated at their angle. The mucous membrane is covered with scaly epithelium.

The **lacrimal sac** is the upper dilated extremity of the nasal duct, and is lodged in a deep groove formed by the lacrimal bone and nasal process of the superior maxillary. It is oval in form, its upper extremity being closed in and rounded, whilst below it is continued into the nasal duct. It is covered by a fibrous expansion derived from the tendo oculi, and on the inner side it is crossed by the Tensor tarsi muscle (Horner's muscle, page 397), which is attached to the ridge on the lacrimal bone.

Structure.—It consists of a fibrous elastic coat, lined internally by mucous membrane, the latter being continuous, through the lacrimal canals, with the mucous lining of the conjunctiva, and, through the nasal duct, with the pituitary membrane of the nose.

The **nasal duct** is a membranous canal, about three-quarters of an inch in length, which extends from the lower part of the lachrymal sac to the inferior meatus of the nose, where it terminates by a somewhat expanded orifice, provided with an imperfect valve, the *valve of Hasner*, formed by the mucous membrane. It is contained in an osseous canal formed by the superior maxillary, the lachrymal, and the inferior turbinated bones, is narrower in the middle than at each extremity, and takes a direction downward, backward, and a little outward. It is lined by mucous membrane, which is continuous below with the pituitary lining of the nose. This membrane in the lachrymal sac and nasal duct is covered with ciliated epithelium as in the nose.

Surface Form.—The palpebral fissure, or opening between the eyelids, is elliptical in shape, and differs in size in different individuals and in different races of mankind. In the Mongolian races, for instance, the opening is very small, merely a narrow fissure, and this makes the eyeball appear small in these races, whereas the size of the eye is relatively very constant. The normal direction of the fissure is slightly oblique, in a direction upward and outward, so that the outer angle is on a slightly higher level than the inner. This is especially noticeable in the Mongolian races, in whom, owing to the upward projection of the malar bone and the shortness of the external angular process of the frontal bone, the tarsal plate of the upper lid is raised at its outer part and gives an oblique direction to the palpebral fissure.

When the eyes are directed forward, as in ordinary vision, the upper part of the cornea is covered by the upper lid, and the lower margin of the cornea corresponds to the level of the lower lid, so that about the lower three-fourths of the cornea is exposed under ordinary circumstances. On the margins of the lids, about a quarter of an inch from the inner canthus, are two small openings, the *puncta lachrymalia*, the commencement of the lachrymal canals. They are best seen by everted the eyelids. In the natural condition they are in contact with the conjunctiva of the eyeball, and are maintained in this position by the Tensor tarsi muscle, so that the tears running over the surface of the globe easily find their way into the lachrymal canals. The position of the lachrymal sac into which the canals open is indicated by a little tubercle (page 226), which is plainly to be felt on the lower margin of the orbit. The lachrymal sac lies immediately above and to the inner side of this tubercle, and a knife passed through the skin in this situation would open the cavity. The position of the lachrymal sac may also be indicated by the tendo oculi or internal tarsal ligament. If both lids be drawn outward, so as to tense the skin at the inner angle, a prominent cord will be seen beneath the tightened skin. This is the *tendo oculi*, which lies immediately over the lachrymal sac, bisecting it, and thus forming a useful guide to its situation. A knife entered immediately beneath the tense cord would open the lower part of the sac. A probe introduced through this opening can be readily passed downward through the duct into the inferior meatus of the nose. The direction of the duct is downward, outward, and backward, and this course should be borne in mind in passing the probe, otherwise the point may be driven through the thin bony walls of the canal. A convenient plan is to direct the probe in such a manner that if it were pushed onward it would strike the first molar tooth of the lower jaw on the same side of the body. In other words, the surgeon standing in front of his patient should carry in his mind the position of the first molar tooth, and should push his probe onward in such a way as if he desired to reach this structure.

Beneath the internal angular process of the frontal bone the pulley of the Superior oblique muscle of the eye can be plainly felt by pushing the finger backward between the upper and inner angle of the eye and the roof of the orbit; passing backward and outward from this pulley, the tendon can be felt for a short distance.

Surgical Anatomy.—The eyelids are composed of various tissues, and consequently are liable to a variety of diseases. The skin which covers them is exceedingly thin and delicate, and is supported on a quantity of loose and lax subcutaneous tissue which contains no fat. In consequence of this it is very freely movable, and is liable to be drawn down by the contraction of neighboring cicatrices, and thus produce an eversion of the lid known as *ectropion*. Inversion of the lids (*entropion*) from spasm of the Orbicularis palpebrarum or from chronic inflammation of the palpebral conjunctiva may also occur. The eyelids are richly supplied with blood, and are often the seat of vascular growths, such as naevi. Rodent ulcer also frequently commences in this situation. The loose cellular tissue beneath the skin is liable to become extensively infiltrated either with blood or inflammatory products, producing very great swelling. Even from very slight injuries to this tissue the extravasation of blood may be so great as to produce considerable swelling of the lids and complete closure of the eye, and the same is the case when inflammatory products are poured out. The follicles of the eyelashes or the sebaceous glands associated with these follicles may be the seat of inflammation, constituting the ordinary "sty." The Meibomian glands are affected in the so-called "tarsal tumor;" the tumor, according to some, being caused by the retained secretion of these glands; by others it is believed to be a neoplasm connected with the gland. The ciliary follicles are liable to become inflamed, constituting the disease known as *blepharitis ciliaris*, or "blear-eye." Irregular or disorderly growth of the eyelashes not unfrequently occurs, some of them being turned toward the eyeball and producing inflammation and ulceration of the cornea, and possibly eventually complete destruction of the eye. The Orbicularis palpebrarum may be the seat of spasm, either in the form of slight quiv-

ering of the lids or repeated twitchings, most commonly due to errors of refraction in children, or more continuous spasm, due to some irritation of the fifth or seventh cranial nerve. The Orbicularis may be paralyzed, generally associated with paralysis of the other facial muscles. Under these circumstances the patient is unable to close the lids, and, if he attempts to do so, rolls the eyeball upward under the upper lid. The tears overflow from displacement of the lower lid, and the conjunctiva and cornea, being constantly exposed and the patient being unable to wink, become irritated from dust and foreign bodies. In paralysis of the Levator palpebræ superioris there is drooping of the upper eyelid and other symptoms of implication of the third nerve. The eyelids may be the seat of bruises, wounds, or burns. In these latter injuries adhesions of the margins of the lids to each other or adhesion of the lids to the globe may take place. The eyelids are sometimes the seat of emphysema after fracture of some of the thin bones forming the inner wall of the orbit. If shortly after such an injury the patient blows his nose, air is forced from the nostril through the lacerated structures into the connective tissue of the eyelids, which suddenly swell up and present the peculiar crackling characteristic of this affection.

The lachrymal gland is occasionally, though rarely, the seat of inflammation, either acute or chronic; it is also sometimes the seat of tumors, benign or malignant, and for these may require removal. This may be done by an incision through the skin just below the eyebrow, and the gland, being invested with a special capsule of its own, may be isolated and removed without opening the general cavity of the orbit. The canaliculi may be obstructed, either as a congenital defect or by some foreign body, as an eyelash or a dacryolith, causing the tears to run over the cheek. The canaliculi may also become occluded as the result of burns or injury; overflow of the tears may in addition result from deviation of the puncta or from chronic inflammation of the lachrymal sac. This latter condition is set up by some obstruction to the nasal duct frequently occurring in tubercular subjects. In consequence of this the tears and mucus accumulate in the lachrymal sac, distending it. Suppuration in the lachrymal sac is sometimes met with; this may be the sequel of a chronic inflammation; or may occur after some of the eruptive fevers in cases where the lachrymal passages were previously quite healthy. It may lead to lachrymal fistula.

THE EAR.

The organ of hearing is divisible into three parts—the external ear, the middle ear or tympanum, and the internal ear or labyrinth.

The **external ear** consists of an expanded portion named *pinna* or *auricle*, and the auditory canal, or *meatus*. The former serves to collect the vibrations of the air by which sound is produced; the latter conducts those vibrations to the tympanum.

The **pinna**, or **auricle** (Fig. 498), is of an ovoid form, with its larger end directed upward. Its outer surface is irregularly concave, directed slightly forward, and presents numerous eminences and depressions which result from the foldings of its fibro-cartilaginous element. To each of these names have been assigned. Thus the external prominent rim of the auricle is called the *helix*. Another curved prominence, parallel with and in front of the helix, is called the *antihelix*; this bifurcates above, so as to enclose a triangular depression, the *fossa of the antihelix*. The narrow curved depression between the helix and antihelix is called the *fossa of the helix* (*fossa innominata* or *scaphoidea*); the antihelix describes a curve round a deep, capacious cavity, the *concha*, which is partially divided into two parts by the commencement of the helix. In front of the concha, and projecting backward over the meatus, is a small pointed eminence, the *tragus*, so called from its being generally covered on its under surface with a tuft of hair resembling a goat's beard. Opposite the tragus, and separated from it by a deep notch (*incisura intertragica*) is a small tubercle, the *antitragus*. Below this is the *lobule*, composed of tough areolar and adipose tissue, wanting the firmness and elasticity of the rest of the pinna.

Structure of the Pinna.—The pinna is composed of a thin plate of yellow fibro-cartilage covered with integument, and connected to the surrounding parts by the extrinsic ligaments and muscles, and to the commencement of the external auditory canal.

The *integument* is thin, closely adherent to the cartilage, and furnished with sebaceous glands, which are most numerous in the concha and scaphoid fossa.

The *cartilage of the pinna* consists of one single piece: it gives form to this part of the ear, and upon its surface are found all the eminences and depressions above described. It does not enter into the construction of all parts of the auricle: thus it does not form a constituent part of the lobule; it is deficient

also between the tragus and beginning of the helix, the notch between them being filled up by dense fibrous tissue. At the front part of the pinna, where the helix bends upward, is a small projection of cartilage, called the *process of the helix*. The cartilage of the pinna presents several intervals or fissures in its substance which partially separate the different parts. The fissure of the helix is a short vertical slit situated at the fore part of the pinna, immediately behind a small conical projection of cartilage, opposite the first curve of the helix (process of the helix). Another fissure, the fissure of the tragus, is seen upon the anterior surface of the tragus. The antihelix is divided below, by a deep fissure, into two parts: one part terminates by a pointed, tail-like extremity (*processus caudatus*); the other is continuous with the antitragus. The cartilage of the

FIG. 499.—The pinna, or auricle.
Outer surface.

FIG. 500.—The muscles of the pinna.

pinna is very pliable, elastic, of a yellowish color, and belongs to that form of cartilage which is known under the name of yellow fibro-cartilage.

The *ligaments of the pinna* consist of two sets: 1. The extrinsic set, or those connecting it to the side of the head. 2. The intrinsic set, or those connecting the various parts of its cartilage together.

The *extrinsic ligaments*, the most important, are two in number, anterior and posterior. The *anterior ligament* extends from the process of the helix to the root of the zygoma. A few fibres connect the tragus to the root of the zygoma. The *posterior ligament* passes from the posterior surface of the concha to the outer surface of the mastoid process of the temporal bone.

The *intrinsic ligaments* are also two in number. Of these, one is a strong fibrous band stretching across from the tragus to the commencement of the helix, completing the meatus in front and partly encircling the boundary of the concha; the other extends between the concha and the *processus caudatus*.

The *muscles of the pinna* (Fig. 477) consist of two sets: 1. The *extrinsic*, which connect it with the side of the head, moving the pinna as a whole—viz. the *Attollens*, *Attrahens*, and *Retrahens aurem* (page 396); and 2. The *intrinsic*, which extend from one part of the auricle to another—viz.:

Helicis major.
Helicis minor.
Tragicus.

Antitragicus.
Transversus auriculæ.
Obliquus auris.

The *Musculus helix major* is a narrow vertical band of muscular fibres, situated upon the anterior margin of the helix. It arises below from the process of the helix, and is inserted into the anterior border of the helix, just where it is about to curve backward. It is pretty constant in its existence.

The *Musculus helix minor* is an oblique fasciculus, attached to that part of the helix which commences from the bottom of the concha.

The *Tragicus* is a short, flattened band of muscular fibres situated upon the outer surface of the tragus, the direction of its fibres being vertical.

The *Antitragicus* arises from the outer part of the antitragus: its fibres are inserted into the processus caudatus of the helix. This muscle is usually very distinct.

The *Transversus auriculæ* is placed on the cranial surface of the pinna. It consists of radiating fibres, partly tendinous and partly muscular, extending from the convexity of the concha to the prominence corresponding with the groove of the helix.

The *Obliquus auris* (Todd) consists of a few fibres extending from the upper and back part of the concha to the convexity immediately above it.

The *arteries of the pinna* are—the posterior auricular from the external carotid, the anterior auricular from the temporal, and an auricular branch from the occipital artery.

The *veins* accompany the corresponding arteries.

The *nerves* are—the auricularis magnus, from the cervical plexus; the posterior auricular, from the facial to the muscles of the pinna; the auricular branch of the pneumogastric; the auriculo-temporal branch of the inferior maxillary nerve; the occipitalis minor from the cervical plexus; and the occipitalis major or internal branch of the posterior division of the second cervical nerve.

The **Auditory Canal** (*meatus auditorius externus*) (Fig. 500) extends from the bottom of the concha to the membrana tympani. It is about an inch and a quarter in length, its direction is obliquely forward and inward, and it is slightly curved upon itself, so as to be higher in the middle than at either extremity. It forms an oval cylindrical canal, the greatest diameter being in the vertical direction at the external orifice, but in the transverse direction at the tympanic end. The calibre of the canal is narrowest about the middle. The membrana tympani, which occupies the termination of the meatus, is obliquely directed, in consequence of which the floor of the canal is longer than the roof, and the anterior wall longer than the posterior. The auditory canal is formed partly by cartilage and membrane, and partly by bone, and is covered by skin.

The *cartilaginous portion* is about half an inch in length, being rather less than half the canal; it is formed by the cartilage of the concha and tragus, prolonged inward, and firmly attached to the circumference of the auditory process of the temporal bone. The cartilage is deficient at its upper and back part, its place being supplied by fibrous membrane. This part of the canal is rendered extremely movable by two or three deep fissures (*incisuræ Santorini*), which extend through the cartilage in a vertical direction.

The *osseous portion* is about three-quarters of an inch in length, and narrower than the cartilaginous portion. It is directed inward and a little forward, forming a slight curve in its course, the convexity of which is upward and backward. Its inner end, which communicates, in the dry bone, with the cavity of the tympanum, is smaller than the outer and sloped, the anterior wall projecting beyond the posterior about two lines; it is marked, except at its upper part, by a narrow groove for the insertion of the membrana tympani. Its outer end is dilated, and rough, in the greater part of its circumference, for the attachment of the cartilage of the pinna. Its vertical transverse section is oval, the greatest diameter being from above downward. The front and lower parts of this canal are formed by a curved plate of bone, which, in the fœtus, exists as a separate ring (tympanic plate), incomplete at its upper part.

The *skin* lining the meatus is very thin, adheres closely to the cartilaginous

and osseous portion of the tube, and covers the surface of the membrana tympani, forming its outer layer. After maceration the thin pouch of epidermis, when withdrawn, preserves the form of the meatus. In the thick subcutaneous tissue of the cartilaginous part of the meatus are numerous ceruminous glands, which

FIG. 501.—A front view of the organ of hearing. Right side.

secrete the ear-wax. They resemble in structure sweat-glands, and their ducts open on the surface of the skin.

The arteries supplying the meatus are branches from the posterior auricular, internal maxillary, and temporal.

The nerves are chiefly derived from the auriculo-temporal branch of the inferior maxillary nerve.

Surface Form.—At the point of junction of the osseous and cartilaginous portions the tube forms an obtuse angle, which projects into the tube at its antero-inferior wall. This produces a sort of constriction in this situation, and renders it the narrowest portion of the canal—an important point to be borne in mind in connection with the presence of foreign bodies in the ears. The cartilaginous is connected to the bony part by fibrous tissue, which renders the outer part of the tube very movable, and therefore by drawing the pinna upward and backward the canal is rendered almost straight. At the external orifice are a few short, crisp hairs which serve to prevent the entrance of small particles of dust, or flies or other insects. In the external auditory meatus the secretion of the ceruminous glands serves to catch any small particles which may find their way into the canal, and prevent their reaching the membrana tympani, where their presence might excite irritation. In young children the meatus is very short, the osseous part being very deficient, and consisting merely of a bony ring (the *tympanic plate*), which supports the membrana tympani. In the fetus the osseous part is entirely absent. The shortness of the canal in children should be borne in mind in introducing the aural speculum, so that it be not pushed in too far, at the risk of injuring the membrana tympani; indeed, even in the adult the speculum should never be introduced beyond the constriction which marks the junction of the osseous and cartilaginous portions. In using this instrument it is advisable that the pinna should be drawn upward, backward, and a little outward, so as to render the canal as straight as possible, and thus assist the operator in obtaining, by the aid of reflected light, a good view of the membrana tympani. Just in front of the membrane is a well-marked depression, situated on the floor of the canal and bounded by a somewhat prominent ridge; in this foreign bodies may become lodged. By aid of the speculum, combined with traction of the auricle upward and backward, the whole of the membrana tympani is rendered visible. It is a pearly-gray membrane, slightly glistening in the adult, placed obliquely, so as to form with the floor of the meatus a very acute angle, while with the roof it forms an obtuse angle. At birth it is more horizontal, situated in almost the same plane as the base of the skull. About midway between the anterior and posterior margins of the membrane, and extending from the centre obliquely upward, is a reddish-yellow streak: this is the handle of the malleus, which is inserted into the membrane. At the upper part of this streak, close to the roof of the meatus, a little white rounded prominence is plainly to be seen; this is the *processus brevis* of the malleus, projecting against the membrane. The membrana tympani does not present a plane surface; on the contrary, its centre is drawn inward, on account of its connection with the handle of the malleus, and thus the external surface is rendered concave.

Middle Ear, or Tympanum.

The **middle ear**, or **tympanum**, is an irregular cavity, compressed from without inward, and situated within the petrous bone. It is placed above the jugular fossa; the carotid canal lying in front, the mastoid cells behind, the meatus auditorius externally, and the labyrinth internally. It is filled with air, and communicates with the pharynx by the Eustachian tube. The tympanum is traversed by a chain of movable bones, which connect the membrana tympani with the labyrinth, and serve to convey the vibrations communicated to the membrana tympani across the cavity of the tympanum to the internal ear.

The *cavity of the tympanum* measures about five lines from before backward, three lines in the vertical direction, and between two and three in the transverse, being a little broader behind and above than it is below and in front. It is bounded externally by the membrana tympani and meatus, internally, by the outer surface of the internal ear, and communicates, behind, with the mastoid cells, and in front with the Eustachian tube and canal for the Tensor tympani. Its roof and floor are formed by thin osseous laminae, the one forming the roof being a thin plate situated on the anterior surface of the petrous portion of the temporal bone, close to its angle of junction with the squamous portion of the same bone.

The **roof** is broad, flattened, and formed of a thin plate of bone which separates the cranial and tympanic cavities.

The **floor** is narrow, and corresponds to the jugular fossa, which lies beneath. It presents, near the inner wall, a small aperture for the passage of Jacobson's nerve.

The **outer wall** is formed mainly by the membrana tympani, partly by the ring of bone into which this membrane is inserted. Close to it are three small apertures—the iter chordæ posterius, the Glaserian fissure, and the iter chordæ antierius.

The *aperture of the iter chordæ posterius* is in the angle of junction between the posterior and external walls of the tympanum, immediately behind the membrana tympani and on a level with its centre; it leads into a minute canal, which descends in front of the aqueductus Fallopii and terminates in that canal near the stylo-mastoid foramen. Through it the chorda tympani nerve enters the tympanum.

The *Glaserian fissure* opens just above and in front of the ring of bone into which the membrana tympani is inserted; in this situation it is a mere slit about a line in length. It lodges the long process of the malleus and gives passage to some tympanic vessels.

The *aperture of the iter chordæ antierius* is seen just above the preceding fissure; it leads into a canal (*canal of Huguier*), which runs parallel with the Glaserian fissure. Through it the chorda tympani nerve leaves the tympanum.

The **internal wall of the tympanum** (Fig. 502) is vertical in direction and looks directly outward. It presents for examination the following parts:

Fenestra ovalis.	Ridge of the aqueductus Fallopii.
Fenestra rotunda.	Pyramid.
Promontory.	Opening for the Stapedius.

The *fenestra ovalis* is a reniform opening leading from the tympanum into the vestibule; its long diameter is directed horizontally, and its convex border is upward. The opening in the recent state is occupied by the base of the stapes, which is connected to the margin of the foramen by an annular ligament.

The *fenestra rotunda* is an aperture placed at the bottom of a funnel-shaped depression leading into the cochlea. It is situated below and rather behind the fenestra ovalis, from which it is separated by a rounded elevation, the *promontory*; it is closed in the recent state by a membrane (*membrana tympani secundaria*, Scarpa). This membrane is concave toward the tympanum, convex toward the cochlea. It consists of three layers: the external, or mucous, derived from the mucous lining of the tympanum; the internal, or serous, from the lining membrane of the cochlea; and an intermediate, or fibrous layer.

The *promontory* is a rounded hollow prominence, formed by the projection outward of the first turn of the cochlea; it is placed between the fenestræ, and is furrowed on its surface by three small grooves which lodge branches of the tympanic plexus.

The rounded eminence of the *aqueductus Fallopii*, the prominence of the bony canal in which the portio dura is contained, traverses the inner wall of the tympanum above the fenestra ovalis, and behind that opening curves nearly vertically downward along the posterior wall.

The *pyramid* is a conical eminence situated immediately behind the fenestra ovalis, and in front of the vertical portion of the eminence above described; it is hollow in the interior, and contains the Stapedius muscle; its summit projects forward toward the fenestra ovalis, and presents a small aperture which transmits the tendon of the muscle. The cavity in the pyramid is prolonged into a minute canal, which communicates with the aqueductus Fallopii and transmits the nerve which supplies the Stapedius.

The posterior wall of the tympanum is wider above than below, and presents for examination the

Openings of the mastoid cells.

These consist of one large irregular aperture and several smaller openings.

FIG. 502.—View of inner wall of tympanum. (Enlarged.)

situated at the upper part of the posterior wall; they lead into canals which communicate with large irregular cavities contained in the interior of the mastoid process. These cavities vary considerably in number, size, and form; they are lined by mucous membrane continuous with that lining the cavity of the tympanum.

The anterior wall of the tympanum is wider above than below; it corresponds with the carotid canal, from which it is separated by a thin plate of bone, perforated by the tympanic branch of the internal carotid. It presents for examination the

Canal for the Tensor tympani.

Orifice of the Eustachian tube.

The processus cochleariformis.

The orifice of the canal for the Tensor tympani and the orifice of the Eustachian tube are situated at the upper part of the anterior wall, being separated from each other by a thin, delicate, horizontal plate of bone, the *processus cochleariformis*. These canals run from the tympanum, forward, inward, and a little downward, to the retiring angle between the squamous and petrous portions of the temporal bone.

The canal for the *Tensor tympani* is the superior and the smaller of the two: it is rounded, and lies beneath the upper surface of the petrous bone, close to the

hiatus Fallopii. The tympanic end of this canal forms a conical eminence which is prolonged backward into the cavity of the tympanum, and is perforated at its summit by an aperture which transmits the tendon of the muscle contained in it. This eminence is sometimes called the *anterior pyramid*. The canal contains the Tensor tympani muscle.

The *Eustachian tube* is the channel through which the tympanum communicates with the pharynx. Its length is from an inch and a half to two inches, and its direction downward, forward, and inward. It is formed partly of bone, partly of cartilage and fibrous tissue.

The *osseous portion* is about half an inch in length. It commences in the lower part of the anterior wall of the tympanum, below the processus cochleariformis, and, gradually narrowing, terminates in an oval dilated opening at the angle of junction of the petrous and squamous portions, its extremity presenting a jagged margin which serves for the attachment of the cartilaginous portion.

The *cartilaginous portion*, about an inch in length, is formed of a triangular plate of elastic fibro-cartilage, curled upon itself, an interval being left below, between the margins of the cartilage, which is completed by fibrous and muscular tissue. Its canal is narrow behind, wide, expanded, and somewhat trumpet-shaped in front, terminating by an oval orifice at the upper part and side of the pharynx, behind the back part of the inferior meatus. Through this canal the mucous membrane of the pharynx is continuous with that which lines the tympanum. The mucous membrane is covered with ciliated epithelium.

The *membrana tympani* separates the cavity of the tympanum from the bottom of the external meatus. It is a thin, semi-transparent membrane, nearly oval in form, somewhat broader above than below, and directed very obliquely downward and inward. Its circumference is contained in a groove at the inner end of the meatus, which skirts the circumference of this part, excepting above. The handle of the malleus descends vertically between the inner and middle layers of this membrane as far down as its centre, where it is firmly attached, drawing the membrane inward, so that its outer surface is concave, its inner convex.

Structure.—This membrane is composed of three layers, an external (cuticular), a middle (fibrous), and an internal (mucous). The *cuticular lining* is derived from the integument lining the meatus. The *fibrous layer* consists of fibrous and elastic tissues; some of the fibres radiate from near the centre to the circumference; others are arranged, in the form of a dense circular ring, round the attached margin of the membrane. The *mucous lining* is derived from the mucous lining of the tympanum. The vessels pass to the membrana tympani along the handle of the malleus, and are distributed between its layers.

Ossicles of the Tympanum (Fig. 503).

The tympanum is traversed by a chain of movable bones three in number, the *malleus*, *incus*, and *stapes*. The former is attached to the membrana tympani, the latter to the fenestra ovalis, the incus being placed between the two, to both of which it is connected by delicate articulations.

The **Malleus**, so named from its fancied resemblance to a hammer, consists of a head, neck, and three processes—the handle or manubrium, the processus gracilis, and the processus brevis.

The *head* is the large upper extremity of the bone; it is oval in shape, and articulates posteriorly with the incus, being free in the rest of its extent.

The *neck* is the narrow contracted part just beneath the head, and below this is a prominence to which the various processes are attached.

The *manubrium* is a vertical process of bone which is connected by its outer margin with the membrana tympani. It decreases in size toward its extremity, where it is curved slightly forward, and flattened from within outward. On the inner side, near its upper end, is a slight projection, into which the tendon of the Tensor tympani is inserted.

The *processus gracilis* is a long and very delicate process which passes from the eminence below the neck forward and outward to the Glaserian fissure, to which it is connected by bone and ligamentous fibres.

The *processus brevis* is a slight conical projection which springs from the root of the manubrium, and lies in contact with the membrana tympani.

The **Incus** has received its name from its supposed resemblance to an anvil, but it is more like a bicuspid tooth, with two roots, which differ in length and are widely separated from each other. It consists of a body and two processes.

The *body* is somewhat quadrilateral, but compressed laterally. On the anterior surface of its summit is a deeply concavo-convex facet, which articulates with the malleus; in the fresh state it is covered with cartilage and lined with synovial membrane.

The two processes diverge from one another nearly at right angles.

The *short process*, somewhat conical in shape, projects nearly horizontally backward, and is attached to the margin of the opening leading into the mastoid cells by ligamentous fibres.

The *long process*, longer and more slender than the preceding, descends nearly vertically behind and parallel to the handle of the malleus, and, bending inward, terminates in a rounded globular projection, the *os orbiculare*, or *lenticular process*, which is tipped with cartilage and articulates with the head of the stapes. In the fetus the *os orbiculare* exists as a separate bone, but becomes united to the long process of the incus in the adult.

The **Stapes**, so called from its close resemblance to a stirrup, consists of a head, neck, two branches, and a base.

The *head* presents a depression, tipped with cartilage, which articulates with the *os orbiculare*.

The *neck*, the constricted part of the bone below the head, receives the insertion of the Stapedius muscle.

The *two branches (crura)* diverge from the neck, and are connected at their extremities by a flattened, oval-shaped plate (the *base*), which forms the foot of the stirrup, and is fixed to the margin of the fenestra ovalis by ligamentous fibres.

Ligaments of the Ossicula.—These small bones are connected with each other and with the walls of the tympanum by ligaments, and moved by small muscles. The articular surfaces of the malleus and incus and the orbicular process of the incus and head of the stapes are covered with cartilage, connected together by delicate capsular ligaments and lined by synovial membrane. The ligaments connecting the ossicula with the walls of the tympanum are four in number—two for the malleus, one for the incus, and one for the stapes.

The *anterior ligament of the malleus* was formerly described by Sömmerring as a muscle (*Laxator tympani*). It is now, however, believed by most observers to consist of ligamentous fibres only. It is attached by one extremity to the neck of the malleus, just above the *processus gracilis*, and by the other to the anterior wall of the tympanum, close to the Glaserian fissure, some of its fibres being prolonged through the fissure.

The *suspensory ligament of the malleus* is a delicate, round bundle of fibres which descends perpendicularly from the roof of the tympanum to the head of the malleus.

The *posterior ligament of the incus* is a short, thick, ligamentous band which connects the extremity of the short process of the incus to the posterior wall of the tympanum, near the margin of the opening of the mastoid cells.

The *annular ligament of the stapes* connects the circumference of the base of this bone to the margin of the fenestra ovalis.

FIG. 503.—The small bones of the ear, seen from the outside. (Enlarged.)

A *suspensory ligament of the incus* has been described by Arnold, descending from the roof of the tympanum to the upper part of the incus, near its articulation with the malleus.

The **muscles of the tympanum** are two :

Tensor tympani.

Stapedius.

The *Tensor tympani*, the larger, is contained in the bony canal above the osseous portion of the Eustachian tube, from which it is separated by the *processus cochleariformis*. It arises from the under surface of the petrous bone, from the cartilaginous portion of the Eustachian tube, and from the osseous canal in which it is contained. Passing backward through the canal, it terminates in a slender tendon which enters the tympanum and makes a sharp bend outward round the extremity of the *processus cochleariformis*, and is inserted into the handle of the malleus near its root. It is supplied by a branch from the otic ganglion.

The *Stapedius* arises from the side of a conical cavity hollowed out of the interior of the pyramid; its tendon emerges from the orifice at the apex of the pyramid, and, passing forward, is inserted into the neck of the stapes. Its surface is aponeurotic, its interior fleshy, and its tendon occasionally contains a slender bony spine, which is constant in some mammalia. It is supplied by the tympanic branch of the facial nerve.

Actions.—The *Tensor tympani* draws the *membrana tympani* inward and thus heightens its tension. The *Stapedius* draws the head of the stapes backward, and thus causes the base of the bone to rotate on a vertical axis drawn through its own centre: in doing this the back part of the base would be pressed inward toward the vestibule, while the fore part would be drawn from it. It probably compresses the contents of the vestibule.

The **mucous membrane of the tympanum** is thin, slightly vascular, and continuous with the mucous membrane of the pharynx through the Eustachian tube. It invests the ossicula and the muscles and nerves contained in the tympanic cavity, forms the internal layer of the *membrana tympani*, covers the *foramen rotundum*, and is reflected into the mastoid cells, which it lines throughout. In the tympanum and mastoid cells this membrane is pale, thin, slightly vascular, and covered with ciliated epithelium. In the osseous portion of the Eustachian tube the membrane is thin, but in the cartilaginous portion it is very thick, highly vascular, covered with laminar ciliated epithelium, and provided with numerous mucous glands.

The **arteries supplying the tympanum** are six in number. Three of them are larger than the rest—viz. the tympanic branch of the internal maxillary, which supplies the *membrana tympani*; the Vidian and the stylo-mastoid branch of the posterior auricular, which supplies the back part of the tympanum and mastoid cells. The smaller branches are—the petrosal branch of the middle meningeal, which enters through the *hiatus Fallopii*; a branch from the ascending pharyngeal, and another from the Vidian which pass up the Eustachian tube; and the tympanic branch from the internal carotid, given off in the carotid canal and perforating the thin anterior wall of the tympanum.

The **veins of the tympanum** terminate in the temporo-maxillary vein and in the superior petrosal sinus.

The **nerves of the tympanum** may be divided into—1, those supplying the muscles; 2, those distributed to the lining membrane; 3, branches communicating with other nerves.

Nerves to Muscles.—The *Tensor tympani* is supplied by a branch from the otic ganglion; the *Stapedius*, by the tympanic branch of the facial (Sömmerring).

The *nerves distributed to the lining membrane* are derived from the tympanic plexus.

The *communications* which take place in the tympanum are between the tympanic branch of the glosso-pharyngeal with the sympathetic and with filaments derived from the *intumescencia ganglioformis* of the facial.

The *tympanic branch of the glosso-pharyngeal* (Jacobson's nerve) enters the

tympanum by an aperture in its floor, close to the inner wall, and divides into branches which are contained in grooves upon the surface of the promontory forming the tympanic plexus.

Its *branches of distribution* are—one to the fenestra rotunda, one to the fenestra ovalis, and one to the lining membrane of the tympanum and Eustachian tube.

Its *branches of communication* are three, and occupy separate grooves on the surface of the promontory. One branch, the *small deep petrosal*, arches forward and downward to the carotid canal to join the carotid plexus. A second, the *long petrosal nerve*, runs forward through a canal close to or in the processus cochleariformis, and enters the foramen lacerum medium, where it joins the carotid plexus of the sympathetic, and generally the large superficial petrosal nerve. The third branch runs upward through the substance of the petrous portion of the temporal bone. In its course it passes by the gangliform enlargement of the facial nerve, and, receiving a connecting filament from it, becomes the *small superficial petrosal nerve*. It then enters the skull through a small aperture, situated external to the hiatus Fallopii on the anterior surface of the petrous bone, courses forward across the base of the skull, and emerges through a foramen in the middle fossa (sometimes through the foramen ovale) and joins the otic ganglion.

The *chorda tympani* is given off from the facial as it passes vertically downward at the back of the tympanum, about a quarter of an inch before its exit from the stylo-mastoid foramen. It passes from below upward and forward in a distinct canal, and enters the cavity of the tympanum through an aperture, *iter chordæ posterius*, on its posterior wall between the opening of the mastoid cells and the attachment of the membrana tympani, and becomes invested with mucous membrane. It passes forward through the cavity of the tympanum, between the handle of the malleus and vertical ramus of the incus, to its anterior inferior angle, and emerges from that cavity through a foramen at the inner end of the Glaserian fissure, which is called the *iter chordæ anterioris*, or canal of Huguier.

The Internal Ear, or Labyrinth.

The *internal ear* is the essential part of the organ, receiving the ultimate distribution of the auditory nerve. It is called the *labyrinth*, from the complexity of its shape, and consists of three parts—the *vestibule*, *semicircular canals*, and *cochlea*. It is formed by a series of cavities channelled out of the substance of the petrous bone, communicating externally with the cavity of the tympanum through the fenestra ovalis and rotunda, and internally with the meatus auditorius internus, which contains the auditory nerve. Within the osseous labyrinth is contained the membranous labyrinth, upon which the ramifications of the auditory nerve are distributed.

The *Vestibule* (Fig. 504) is the common central cavity of communication between the parts of the internal ear. It is situated on the inner side of the tympanum, behind the cochlea, and in front of the semicircular canals. It is somewhat ovoidal in shape from before backward, flattened from within outward, and measures about one-fifth of an inch from before backward, as well as from above downward, being narrower from without inward. On its *outer* or *tympanic wall* is the fenestra ovalis, closed, in the recent state, by the base of the stapes and its annular ligament. On its *inner wall*, at the fore part, is a small circular depression, *fovea hemispherica*, which is perforated, at its anterior and inferior part, by several minute holes (*macula cribrosa*) for the passage of the filaments of the auditory nerve; and behind this depression is a vertical ridge, the *pyramidal eminence* (*crista vestibuli*). At the hinder part of the inner wall is the orifice of the *aqueductus vestibuli*, which extends to the posterior surface of the petrous portion of the temporal bone. It transmits a small vein, and, according to some, contains a tubular prolongation of the lining membrane of the vestibule, which ends in a *cul-de-sac* between the layers of the dura mater within the cranial cavity. On the *upper wall* or *roof* is a transversely oval depression, *fovea semi-elliptica*,

separated from the fovea hemispherica by the pyramidal eminence already mentioned. Behind, the semicircular canals open into the vestibule by five orifices. In front is a large oval opening which communicates with the scala vestibuli of the cochlea by a single orifice, *apertura scale vestibuli cochleæ*.

The **Semicircular canals** are three bony canals situated above and behind the vestibule. They are of unequal length, compressed from side to side, and describe the greater part of a circle. They measure about one-twentieth of an inch in diameter, and each presents a dilatation at one end, called the *ampulla*, which measures more than twice the diameter of the tube. These canals open into the vestibule by five orifices, one of the apertures being common to two of the canals.

The *superior semicircular canal* is vertical in direction, and stretches across the petrous portion of the temporal bone, at right angles to its posterior surface; its arch forms a round projection on the anterior surface of the petrous bone. It describes about two-thirds of a circle. Its outer extremity, which is ampullated, commences by a distinct orifice in the upper part of the vestibule; the opposite end

FIG. 504.—The osseous labyrinth laid open. (Enlarged.)

of the canal, which is not dilated, joins with the corresponding part of the posterior canal, and opens by a common orifice with it in the back part of the vestibule.

The *posterior semicircular canal*, also vertical in direction, is directed backward, nearly parallel to the posterior surface of the petrous bone; it is the longest of the three: its ampullated end commences at the lower and back part of the vestibule, its opposite end joining to form the common canal already mentioned.

The *external or horizontal canal* is the shortest of the three, its arch being directed outward and backward; thus each semicircular canal stands at right angles to the other two. Its ampullated end corresponds to the upper and outer angle of the vestibule, just above the fenestra ovalis; its opposite end opens by a distinct orifice at the upper and back part of the vestibule.

The **Cochlea** bears some resemblance to a common snail-shell: it forms the anterior part of the labyrinth, is conical in form, and placed almost horizontally in front of the vestibule; its apex is directed forward and outward toward the upper and front part of the inner wall of the tympanum; its base corresponds with the anterior depression at the bottom of the internal auditory meatus, and is perforated by numerous apertures for the passage of the cochlear branch of the

auditory nerve. It measures about a quarter of an inch in length, and its breadth toward the base is about the same. It consists of a conical-shaped central axis, the *modiolus* or *columella*; of a canal wound spirally round the axis for two turns and a half, from the base to the apex; and of a delicate lamina (the *lamina spiralis*) contained within the canal, which follows its windings and partially subdivides it into two.

The *central axis*, or *modiolus*, is conical in form, and extends from the base to the apex of the cochlea. Its base is broad, corresponds with the first turn of the cochlea, and is perforated by numerous orifices, which transmit filaments of the cochlear branch of the auditory nerve; the axis diminishes rapidly in size in the second coil, and terminates within the last half-coil, or *cupola*, in an expanded delicate, bony lamella, which resembles the half of a funnel divided longitudinally, and is called the *infundibulum*; the broad part of this funnel is directed toward the summit of the cochlea, and blends with the cupola or last half-turn of the spiral canal of the cochlea. At this point the two larger *scalæ* of the cochlea, the *scala tympani* and *scala vestibuli*, communicate by an opening called the *helicotrema*. The outer surface of the modiolus forms part of the wall of the spiral canal, and is dense in structure; but its centre is channelled, as far as the last half-coil, by numerous branching canals, which transmit nervous filaments in regular succession into the canal of the cochlea or on to the surface of the *lamina spiralis*. One of these, larger than the rest, occupies the centre of the modiolus, and is named the *canalis centralis modioli*; it extends from the base to the extremity of the modiolus, and transmits a small nerve and artery (*arteria centralis modioli*).

The *spiral canal* (Fig. 505) takes two turns and a half round the modiolus. It is about an inch and a half in length, measured along its outer wall, and

FIG. 505.—The cochlea laid open. (Enlarged.)

diminishes gradually in size from the base to the summit, where it terminates in a *cul-de-sac*, the *cupola*, which forms the apex of the cochlea. The commencement of this canal is about the tenth of an inch in diameter; it diverges from the modiolus toward the tympanum and vestibule and presents three openings. One, the *fenestra rotunda*, communicates with the tympanum; in the recent state this aperture is closed by a membrane, the *membrana tympani secundaria*. Another aperture, of an oval form, enters the vestibule. The third is the aperture of the *aqueductus cochleæ*, leading to a minute funnel-shaped canal, which opens on the basilar surface of the petrous bone and transmits a small vein.

The interior of the spiral canal (Fig. 506) is partially divided into two, in the dry state, by a thin bony plate, the *lamina spiralis*, which consists of two thin lamellæ of bone, between which are numerous canals for the passage of nerve-fibres. This lamina projects from the modiolus into the canal, but does not reach more than halfway toward the outer wall of the tube. From its extremity a thin membrane extends to the outer wall, and completes the division of the canal into an upper compartment, the *scala vestibuli*, and a lower one, the *scala tympani*.

By a second membrane a portion of the upper of these two canals is cut off from the rest, constituting the *scala media*. The lamina spiralis ends above in a hook-shaped process which partly bounds the helicotrema. At the point where the osseous lamina is attached to the modiolus is a small canal, which winds round the modiolus, and was denominated by Rosenthal the *canalis spiralis modioli*; it is occupied by a swelling of the cochlear nerve, the *ganglion spirale*, in which

FIG. 506.—Longitudinal section of the cochlea, showing the relations of the scala, the ganglion spirale, etc. S. V. Scala vestibuli. S. T. Scala tympani. S. M. Scala media. L. S. Ligamentum spirale. G. S. Ganglion spirale.

ganglion-cells are found, and from which the nerves pass to the osseous lamina and organ of Corti.

The osseous lamina, as above stated, extends only part of the distance between the modiolus and the outer bony wall of the cochlea. Near its outer end the periosteum on the upper or vestibular surface of the lamina swells up into an elevation which is called the *limbus laminae spiralis* ("denticulate lamina" of Todd and Bowman). The lamina spiralis terminates in a grooved extremity, the *sulcus spiralis*, which presents the form of the letter C: the upper part of the letter, being formed by the overhanging extremity of the limbus, is named the *labium vestibulare*; the lower part, prolonged and tapering, is called the *labium tympanicum* (Fig. 507). From the labium tympanicum a thin membrane extends over to the bony wall of the cochlea, completing the scala tympani. This membrane is called the *membrana basilaris*. At its outer attachment it swells out so as to form a thick triangular structure, which was regarded as a muscle by Todd and Bowman (cochlearis), but is now recognized as ligamentous—the *ligamentum spirale*. Between the labium vestibulare and the attachment of the membrane of Reissner, presently to be described, a very delicate membrane extends over to the outer wall of the cochlea, running nearly parallel to the *membrana basilaris*. It was described by Corti, and covers over the organ which is called after his name, and is therefore called *membrane of Corti*, or *membrana tectoria*. Farther inward, near the commencement of the *limbus laminae spiralis*, another delicate membrane, the *membrane of Reissner*, is attached to the vestibular surface of the periosteum of the osseous lamina and stretches across to the outer wall of the cochlea. The canal which lies below the osseous lamina and *membrana basilaris* is the *scala tympani*; that which is bounded by the osseous lamina and membrane of Reissner, the *scala vestibuli*; while the space between the membrane of Reissner and *membrana basilaris* is generally described as the *Scala media*, *Canalis membranacea*, or *Canalis cochleæ*, and this is the nomenclature which will be used here. Others, however, apply the name *canalis cochleæ* only to the canal

lying between the membrane of Reissner and the membrana tectoria, which contains no object for description, while the space lying between the membrana tectoria and membrana basilaris is described by itself as a fourth canal—the *ductus cochlearis* or *ductus auditorius*.¹ The latter is the space in which the *organ of Corti*² is contained. This organ (Fig. 507) is situated upon the membrana basilaris, and appears at first sight as a papilla, winding spirally with the turns of this membrane throughout the whole length of the cochlea, from which circumstance it has been designated the *papilla spiralis*. More accurately viewed, it is seen to

FIG. 507.—Floor of scala media, showing the organ of Corti, etc.

be composed of a remarkable arrangement of cells which may be likened to the keyboard of a pianoforte. Of these cells, the two central ones are rod-like bodies, and are called the inner and outer *rods of Corti*. They are placed erect on the basilar membrane at some little distance from each other, the space between them being denominated the *zona arcuata*; they are inclined toward each other, so as to meet at their opposite extremities and form a series of arches roofing over the *zona arcuata*, thus forming a minute tunnel between them and the basilar membrane, which ascends spirally through the whole length of the cochlea. They are estimated at over three thousand in number.

The inner rods, which are more numerous than the outer ones, rest on the basilar membrane, close to the labium tympanicum; they project obliquely forward and outward, and terminate above in expanded extremities, which resemble in shape the upper end of the ulna, with its sigmoid cavity, coronoid and olecranon processes. On the outer side of the rod, in the angle formed between it and the basilar membrane, is a protoplasmic cell, whilst on the inner side is a row of epithelial cells surmounted by a brush of fine, stiff, hair-like processes, these cells being continuous with the cubical cells lining the sulcus spiralis.

The outer rods also rest by a broad foot on the basilar membrane; they incline forward and inward, and their upper extremity resembles the head and bill of a swan, the head fitting into the concavity—the analogue of the sigmoid cavity—of one or more of the internal rods, and the bill resting against the phalanges of the lamina reticularis, presently to be described.

In the head of these outer rods is an oval portion, where the fibres of which the rod appears to be composed are deficient, and which stains more deeply with carmine than the rest of the rod. This is supposed to represent the nucleus of the cell from which the rod was originally developed. At the base of the rod, on its internal side—that is to say, in the angle formed by the rod with the basilar membrane—is a similar protoplasmic cell to that found on the outer side of the base of the inner rod, whilst external to the outer rod are three or four successive

¹ In reading the older descriptions of the organ of hearing the student must bear in mind that the membranes bounding the ductus auditorius, together with the organ contained between them, were described together as the "*lamina spiralis membranacea*," while the membrane of Reissner was not recognized, the parts being, in fact, as shown in the second turn of the cochlea on the right hand of Fig. 506.

² Corti's original paper is in the *Zeitschrift f. Wissen. Zool.*, iii. 109.

rows of epithelial cells, more elongated than those found on the internal side of the inner rod, but, like them, furnished with minute hairs or cilia. These are termed the *outer hair-cells*, in contradistinction to the inner set, which are termed the *inner hair-cells*. They are attached by their bases to the basilar membrane, whilst from the opposite extremity a brush of hairs or cilia projects through the reticular membrane. They are continuous externally with the cubical cells on the lateral part of the basilar membrane.

The *reticular lamina* or *membrane of Kölliker* is a delicate framework perforated by rounded holes. It extends from the inner rods of Corti to the external row of the outer hair-cells, and is formed by several rows of "minute fiddle-shaped cuticular structures," called *phalanges*, between which are holes for the projection of the cilia of the outer hair-cells.

Covering over these structures, but not touching them, is the *membrana tectoria*, or membrane of Corti, which is attached to the vestibular surface of the lamina spiralis close to the attachment of the membrane of Reissner; it courses over the denticulate lamina, and, passing outward parallel to the basilar membrane, is blended with the ligamentum spirale on the outer wall of the spiral canal.¹

The *inner surface of the osseous labyrinth* is lined by an exceedingly thin fibro-serous membrane, analogous to a periosteum from its close adhesion to the inner surfaces of these cavities, and performing the office of a serous membrane by its free surface. It lines the vestibule, and from this cavity is continued into the semicircular canals and the scala vestibuli of the cochlea, and through the helicotrema into the scala tympani. A delicate tubular process is prolonged along the aqueduct of the vestibule to the inner surface of the dura mater. This membrane is continued across the fenestra ovalis and rotunda, and consequently has no communication with the lining membrane of the tympanum. Its attached surface is rough and fibrous, and closely adherent to the bone; its free surface is smooth and pale, covered with a layer of epithelium, and secretes a thin, limpid fluid, the *aqua labyrinthi*, *liquor Cotunnii*, or *perilymph* (Blainville).

The *scala media* is closed above and below. The upper blind extremity is attached to the cupola at the upper part of the helicotrema; the lower end fits into the angle at the commencement of the osseous lamina on the floor of the vestibule. Near this blind extremity, the *scala media* receives the *canalis reuniens* (Fig. 508), a very delicate canal by which the ductus cochlearis is brought into continuity with the saccule.

The Membranous Labyrinth.

The membranous labyrinth (Fig. 508) is a closed membranous sac, containing fluid, on the walls of which the ramifications of the auditory nerve are distributed. It has the same general form as the vestibule and semicircular canals in which it is enclosed and to which it is limited; but is considerably smaller, and separated from their lining membrane by the perilymph.

The *vestibular portion* consists of two sacs, the utricle and the saccule.

The *utricle* is the larger of the two, of an oblong form, compressed laterally, and occupies the upper and back part of the vestibule, lying in contact with the fovea semi-elliptica. Numerous filaments of the auditory nerve are distributed on the wall of this sac, and its cavity communicates behind with the membranous semicircular canals by five orifices.

The *saccule* is the smaller of the two vestibular sacs; it is globular in form, lies in the fovea hemispherica near the opening of the vestibular scala of the cochlea, and receives numerous nervous filaments which enter from the bottom of the depression in which it is contained. Its cavity is apparently distinct from that of the utricle.

The *membranous semicircular canals* are about one-third the diameter of the

¹ In Fig. 507 only the inner half of the membrane is represented.

osseous canals, but in number, shape, and general form they are precisely similar; they are hollow, and open by five orifices into the utricle, one opening being common to two canals. Their ampullæ are thicker than the rest of the tubes, and nearly fill the cavities in which they are contained.

The membranous labyrinth is held in position by numerous fibrous bands which stretch across the space between the membranous and bony labyrinths. These fibrous bands convey the blood-vessels and nervous filaments distributed to the utricle, to the sacculæ, and to the ampulla of each canal. The nerves enter the vestibule through the minute apertures on its inner wall.

Structure.—The wall of the membranous labyrinth is semi-transparent, and consists of three layers. The *outer layer* is a loose and flocculent structure, apparently composed of ordinary fibrous tissue, containing blood-vessels and numerous pigment-cells analogous to those in the pigment-coat of the retina. The *middle layer*, thicker and more transparent, bears some resemblance to the hyaloid

FIG. 568.—The membranous labyrinth. (Enlarged.)

membrane, but it presents on its internal surface numerous papilliform projections, and on the addition of acetic acid presents an appearance of longitudinal fibrillation and elongated nuclei. The *inner layer* is formed of polygonal nucleated epithelial cells, which secrete the endolymph.

The *endolymph* (*liquor Scarpa*) is a limpid serous fluid which fills the membranous labyrinth; in composition it closely resembles the perilymph.

The *otoliths* are two small rounded bodies consisting of a mass of minute crystalline grains of carbonate of lime, held together in a mesh of delicate fibrous tissue, and contained in the walls of the utricle and saccule, opposite the distribution of nerves. A calcareous material is also, according to Bowman, sparingly scattered in the cells lining the ampulla of each semicircular canal.

The *arteries of the labyrinth* are—the internal auditory, from the basilar; the stylo-mastoid, from the posterior auricular; and, occasionally, branches from the occipital. The internal auditory divides at the bottom of the internal meatus into two branches, cochlear and vestibular.

The cochlear branch subdivides into from twelve to fourteen twigs, which traverse the canals in the modiolus, and are distributed, in the form of a capillary network, in the substance of the lamina spiralis.

The vestibular branches accompany the nerves, and are distributed, in the form of a minute capillary network, in the substance of the membranous labyrinth.

The *veins* (auditory) of the vestibule and semicircular canals accompany the arteries, and, receiving those of the cochlea at the base of the modiolus, terminate in the superior petrosal sinus.

The *auditory nerve*, the special nerve of the sense of hearing, divides, at the

bottom of the internal auditory meatus, into two branches, the cochlear and vestibular. The trunk of the nerve, as well as the branches, contains numerous ganglion-cells with caudate prolongations.

The vestibular nerve, the posterior of the two, divides into three branches—superior, middle, and inferior.

The superior vestibular branch, the largest, divides into numerous filaments, which pass through minute openings at the upper and back part of the *cul-de-sac* at the bottom of the meatus, and, entering the vestibule, are distributed to the utricle and to the ampulla of the external and superior semicircular canals.

The middle vestibular branch consists of numerous filaments, which enter the vestibule by a smaller cluster of foramina placed below those above mentioned, and which correspond to the bottom of the fovea hemispherica; they are distributed to the saccule.

The inferior and smallest branch passes backward in a canal behind the foramina for the nerves of the saccule, and is distributed to the ampulla of the posterior semicircular canal.

The nervous filaments enter the ampullary enlargements at a deep depression seen on their external surface, with a corresponding elevation when seen from within; the nerve-fibres ending in loops and in free extremities. In the utricle and saccule the nerve-fibres spread out, some blending with the calcareous matter; others, radiating on the inner surface of the wall of each cavity, become blended with a layer of nucleated cells and terminate in a thin fibrous film.

The cochlear nerve divides into numerous filaments at the base of the modiolus, which ascend along its canals, and then, bending outward at right angles, pass between the plates of the bony lamina spiralis, close to its tympanic surface. Between the plates of the spiral lamina the nerves form a plexus which contains ganglion cells forming the ganglion spirale. From this ganglion delicate filaments pass between the layers of the osseous lamina to the sulcus spiralis and pass outward to the organ of Corti. Their exact termination is uncertain. Waldeyer describes them as collected into two groups, one group ending in the outer and the other in the inner hair-cells.

Surgical Anatomy.—Malformations, such as imperfect development of the external parts, absence of the meatus, or supernumerary auricles, are occasionally met with. Or the pinna may present a congenital fistula which is due to defective closure of the first visceral cleft, or rather of that portion of it which is not concerned in the formation of the Eustachian tube, tympanum, and meatus. The skin of the auricle is thin and richly supplied with blood, but in spite of this it is frequently the seat of frost-bite, due to the fact that it is much exposed to cold, and lacks the usual covering of subcutaneous fat found in most other parts of the body. A collection of blood is sometimes found between the cartilage and perichondrium (*hematoma auris*), usually the result of traumatism, but not necessarily due to this cause. It is said to occur most frequently in the ears of the insane. Keloid sometimes grows in the auricle around the puncture made for earrings, and epithelioma occasionally affects this part. Deposits of urate of soda are often met with in the pinna in gouty subjects.

The external auditory meatus can be most satisfactorily examined by light reflected down a funnel-shaped speculum; by gently moving the latter in different directions the whole of the canal and membrana tympani can be brought into view. The points to be noted are, the presence of wax or foreign bodies, the size of the canal, and the condition of the membrana tympani. The accumulation of wax is often the cause of deafness, and may give rise to very serious consequences, causing ulceration of the membrane and even absorption of the bony wall of the canal. Foreign bodies are not infrequently introduced into the ear by children, and, when situated in the first portion of the canal, may be removed with tolerable facility by means of a minute hook or loop of fine wire, with reflected light; but when they have slipped beyond the narrow middle part of the meatus, their removal is in no wise easy, and attempts to effect it, in inexperienced hands, may be followed by destruction of the membrana tympani and possibly the contents of the tympanum. The calibre of the external auditory canal may be narrowed by inflammation of its lining membrane, running on to suppuration; by periostitis; by polyp, sebaceous tumors, and exostoses. The membrana tympani, when seen in a healthy ear, reflects light strongly, and, owing to its peculiar curvature, presents a bright spot of triangular shape at its lower and anterior portion. From the apex of this, proceeding upward and slightly forward, is a white streak formed by the handle of the malleus, while at the upper and middle part of the membrane may be seen a slight projection, caused by the short process of the malleus. In

disease alterations in color, lustre, curvature or inclination, and perforation must be noted. Such perforations may be caused by a blow or a loud report or by a wound.

The upper wall of the meatus is separated from the cranial cavity by a thin plate of bone; the anterior wall is separated from the temporo-maxillary joint and parotid gland by the bone forming the glenoid fossa; and the posterior wall is in relation with the mastoid cells; hence inflammation of the external auditory meatus may readily extend to the membranes of the brain, to the temporo-maxillary joint, or to the mastoid cells; and, in addition to this, blows on the chin may cause fracture of the wall of the meatus.

The nerves supplying the meatus are the auricular branch of the pneumogastric, the auriculo-temporal, and the auricularis magnus. The connections of these nerves explain the fact of the occurrence, in cases of any irritation of the meatus, of constant coughing and sneezing from implication of the pneumogastric, or of yawning from implication of the auriculo-temporal. No doubt also the association of earache with toothache in cancer of the tongue is due to implication of the same nerve, a branch of the fifth, which supplies also the teeth and the tongue. The vessels of the meatus and membrana tympani are derived from the posterior auricular, temporal, and internal maxillary arteries. The upper half of the membrana tympani is much more richly supplied with blood than the lower half. For this reason, and also to avoid the chorda tympani nerve and ossicles, incisions through the membrane should be made at the lower and posterior part.

The principal point in connection with the surgical anatomy of the tympanum is its relations to other parts. Its roof is formed by a thin plate of bone, which, with the dura mater, is all that separates it from the temporo-sphenoidal lobe of the brain. Its floor is immediately above the jugular fossa behind and the carotid canal in front. Its posterior wall presents the openings of the mastoid cells. On its anterior wall is the opening of the Eustachian tube. Thus it follows that in disease of the middle ear we may get subdural abscess, septic meningitis, or abscess of the cerebrum or cerebellum from extension of the inflammation through the bony roof; thrombosis of the lateral sinus, with or without pyæmia, by extension through the floor; or mastoid abscess by extension backward. In addition to this, we may get fatal hæmorrhage from the internal carotid in destructive changes of the middle ear; and in throat disease we may get the inflammation extending up the Eustachian tube to the middle ear. The Eustachian tube is accessible from the nose. If the nose and mouth be closed and an attempt made to expire air, a sense of pressure with dulness of hearing is produced in both ears, from the air finding its way up the Eustachian tube and bulging out the membrana tympani. During the act of swallowing the pharyngeal orifice of the tube, which is normally closed, is opened, probably by the action of the Tensor tympani. This fact was employed by Politzer in devising an easy method of inflating the tube. The nozzle of an india-rubber syringe is inserted into the nostril; the patient takes a mouthful of water and holds it in his mouth; both nostrils are closed with the finger and thumb to prevent the escape of air, and the patient is then requested to swallow; as he does so the air is forced out of the syringe into his nose, and is driven into the Eustachian tube, which is now open. The impact of the air against the membrana tympani can be heard, if the membrane is sound, by means of a piece of india-rubber tubing, one end of which is inserted into the meatus of the patient's ear, the other into that of the surgeon. The direct examination of the Eustachian tube is made by the Eustachian catheter. This is passed along the floor of the nostril, with the curve downward, to the posterior wall of the pharynx. When this is felt, the catheter is to be withdrawn about half an inch, and the point rotated outward through a quarter of a circle, and pushed again slightly backward, when it will enter the orifice of the tube, and will be found to be caught, and air forced into the catheter will be heard impinging on the tympanic membrane if the ears of the patient and surgeon are connected by an india-rubber tube.

THE ORGANS OF DIGESTION.

THE Apparatus for the Digestion of the Food consists of the alimentary canal and of certain accessory organs.

The **alimentary canal** is a musculo-membranous tube, about thirty feet in length, extending from the mouth to the anus, and lined throughout its entire extent by mucous membrane. It has received different names in the various parts of its course: at its commencement, the mouth, we find provision made for the mechanical division of the food (*mastication*), and for its admixture with a fluid secreted by the salivary glands (*insalivation*); beyond this are the organs of deglutition, the pharynx and the œsophagus, which convey the food into that part of the alimentary canal (the stomach) in which the principal chemical changes occur, and in which the reduction and solution of the food take place; in the small intestines the nutritive principles of the food (the *chyle*) are separated, by its admixture with the bile and pancreatic fluid, from that portion which passes into the large intestine, most of which is expelled from the system.

THE MOUTH.

The **mouth** (*oral or buccal cavity*) (Fig. 509) is placed at the commencement of the alimentary canal; it is a nearly oval-shaped cavity, in which the mastication of the food takes place. It is bounded, in front, by the lips; laterally, by the cheeks and alveolar processes of the upper and lower jaws; above, by the hard palate and teeth of the upper jaw; below, by the tongue and by the mucous membrane stretched between the under surface of that organ and the inner surface of the jaws, and by the teeth of the lower jaw; behind, by the soft palate and fauces.

The *mucous membrane* lining the mouth is continuous with the integument at the free margin of the lips and with the mucous lining of the fauces behind; it is of a rose-pink tinge during life, and very thick where it covers the hard parts bounding the cavity. It is covered by stratified epithelium.

The **lips** are two fleshy folds which surround the orifice of the mouth, formed externally of integument and internally of mucous membrane, between which are found the Orbicularis oris muscle, the coronary vessels, some nerves, areolar tissue, and fat, and numerous small labial glands. The inner surface of each lip is con-

nected in the middle line to the gum of the corresponding jaw by a fold of mucous membrane, the *frænum labii superioris* and *inferioris*—the former being the larger of the two.

The *labial glands* are situated between the mucous membrane and the Orbicularis oris round the orifice of the mouth. They are rounded in form, about the size of small peas, their ducts opening by small orifices upon the mucous membrane. In structure they resemble the salivary glands.

The *cheeks* form the sides of the face and are continuous in front with the lips. They are composed externally of integument, internally of mucous membrane, and between the two of a muscular stratum, besides a large quantity of fat, areolar tissue, vessels, nerves, and buccal glands.

The *mucous membrane* lining the cheek is reflected above and below upon the gums, and is continuous behind with the lining membrane of the soft palate.

FIG. 509.—Sectional view of the nose, mouth, pharynx, etc.

Opposite the second molar tooth of the upper jaw is a papilla, the summit of which presents the aperture of the duct of the parotid gland. The principal muscle of the cheek is the Buccinator, but numerous other muscles enter into its formation—viz. the Zygomatici, Risorius Santorini, and Platysma myoides.

The *buccal glands* are placed between the mucous membrane and Buccinator muscle: they are similar in structure to the labial glands, but smaller. Two or three of larger size than the rest are placed between the Masseter and Buccinator muscles; their ducts open into the mouth opposite the last molar tooth. They are called *molar glands*.

The *gums* are composed of a dense fibrous tissue closely connected to the

periosteum of the alveolar processes and surrounding the necks of the teeth. They are covered by smooth and vascular mucous membrane, which is remarkable for its limited sensibility. Around the necks of the teeth this membrane presents numerous fine papillæ, and from this point it is reflected into the alveolus, where it is continuous with the periosteal membrane lining that cavity.

THE TEETH.

The human subject is provided with two sets of teeth, which make their appearance at different periods of life. The first set appear in childhood, and are called the *temporary, deciduous, or milk teeth*. The second set, which also appear at an early period, continue until old age, and are named *permanent*.

The *temporary teeth* are twenty in number—four incisors, two canine, and four molars, in each jaw.

The *permanent teeth* are thirty-two in number—four incisors (two central and two lateral), two canines, four bicuspid, and six molars in each jaw.

General Characters.—Each tooth consists of three portions: the *crown, or body*, projecting above the gum; the *root, or fang*, entirely concealed within the alveolus; and the *neck*, the constricted portion, between the other two.

The *roots of the teeth* are firmly implanted within the alveoli; these depressions are lined with periosteum, which is reflected on to the tooth at the point of the fang and covers it as far as the neck. At the margin of the alveolus the periosteum becomes continuous with the fibrous structure of the gums.

Permanent Teeth.

The *incisors*, or cutting teeth, are so named from their presenting a sharp cutting edge, adapted for biting the food. They are eight in number, and form the four front teeth in each jaw.

The *crown* is directed vertically and is wedge-like in form, being bevelled at the expense of its posterior surface, so as to terminate in a sharp horizontal cutting edge, which, before being subject to attrition, presents three small prominent points. It is convex, smooth, and highly polished in front; concave behind, where it is frequently marked by slight longitudinal furrows.

The *neck* is constricted.

The *fang* is long, single, conical, transversely flattened, thicker before than behind, and slightly grooved on each side in the longitudinal direction.

The *incisors of the upper jaw* are altogether larger and stronger than those of the lower jaw. They are directed obliquely downward and forward. The two central ones are larger than the two lateral, and their free edges are sharp and chisel-like, being bevelled at the expense of their posterior edge: the root is more rounded.

The *incisors of the lower jaw* are smaller than the upper; the two central ones are smaller than the two lateral, and are the smallest of all the incisor teeth.

The *canine teeth (cuspidati)* are four in number—two in the upper and two in the lower jaw, one being placed behind each lateral incisor. They are larger and stronger than the incisors, especially the root, which sinks deeply into the jaw and causes a well-marked prominence upon its surface.

The *crown* is large and conical, very convex in front, a little hollowed and uneven posteriorly, and tapering to a blunted point or cusp, which rises above the level of the other teeth.

The *root* is single, but longer and thicker than that of the incisors, conical in form, compressed laterally, and marked by a slight groove on each side.

The *upper canine teeth* (vulgarly called *eye-teeth*) are larger and longer than the two lower, and situated a little behind them.

The *lower canine teeth* are placed in front of the upper, so that their summits correspond to the interval between the upper canine tooth and the neighboring incisors on each side.

The **bicuspid teeth** (premolars, small, or false molars) are eight in number—four in each jaw, two being placed immediately behind each of the canine teeth. They are smaller and shorter than the canine.

The *crown* is compressed from without inward, and surmounted by two pyramidal eminences, or cusps, separated by a groove; hence their name, *bicuspidate*. The outer of these cusps is larger and more prominent than the inner.

The *neck* is oval.

The *root* is generally single, compressed, and presents a deep groove on each side, which indicates a tendency in the root to become double. The apex is generally bifid.

The *upper bicuspid*s are larger, and present a greater tendency to the division of their roots than the lower; this is especially marked in the second upper bicuspid.

The **molar teeth** (*multicuspidati*, true or large molars) are the largest of the permanent set, and are adapted from the great breadth of their crowns for grinding

FIG. 519.—The permanent teeth. External view.

and pounding the food. They are twelve in number—six in each jaw, three being placed behind each of the posterior bicuspid.

The *crown* is nearly cubical in form, rounded on each of its lateral surfaces, flattened in front and behind, the upper surface being surmounted by four or five tubercles, or cusps (four in the upper, five in the lower molars), separated from each other by a crucial depression; hence their name, *multicuspidati*.

The *neck* is distinct, large, and rounded.

The *root* is subdivided into from two to five fangs, each of which presents an aperture at its summit.

The *first molar tooth* is the largest and broadest of all; its crown has usually five cusps, three outer and two inner. In the upper jaw the root consists of three fangs, widely separated from one another, two being external, the other internal.

The latter is the largest and longest, slightly grooved, and sometimes bifid. In the lower jaw the root consists of two fangs, one being placed in front, the other behind; they are both compressed from before backward, and grooved on their contiguous faces, indicating a tendency to division.

The *second molar* is a little smaller than the first.

The crown has four cusps in the upper and five in the lower jaw.

The root has three fangs in the upper jaw and two in the lower, the characters of which are similar to the preceding tooth.

The *third molar tooth* is called the *wisdom tooth* (*dens sapientie*), from its late appearance through the gum. It is smaller than the others, and its axis is directed inward.

The crown is small and rounded and furnished with three tubercles.

The root is generally single, short, conical, slightly curved, and grooved so as to present traces of a subdivision into three fangs in the upper and two in the lower jaw.

Temporary Teeth.

The **temporary or milk teeth** are smaller, but resemble in form those of the permanent set. The hinder of the two temporary molars is the largest of all the milk teeth, and is succeeded by the second permanent bicuspid. The first upper molar has only three cusps—two external, one internal; the second upper molar has four cusps. The first lower molar has four cusps; the second lower molar

FIG. 511.—The temporary, or milk teeth. External view.

has five. The fangs of the temporary molar teeth are smaller and more diverging than those of the permanent set, but in other respects bear a strong resemblance to them.

Structure of the Teeth.

On making a vertical section of a tooth (Fig. 512) a cavity will be found in the interior. This cavity is situated in the interior of the crown and the centre of each fang, and opens by a minute orifice at the extremity of the latter. The shape of the cavity corresponds somewhat with that of the tooth; it forms what is called the *pulp-cavity*, and contains a soft, highly vascular, and sensitive substance, the *dental pulp*. The pulp consists of a loose connective tissue and cells; it is richly supplied with vessels and nerves, which enter the cavity through the small aperture at the point of each fang. The cells of the pulp are partly found permeating the connective tissue, and partly arranged as a layer on the wall of the pulp-cavity. These latter cells are of two kinds: some, columnar in shape, are named the *odontoblasts of Waldeyer*, and will be referred to hereafter; others, fusiform in shape, are wedged in between the columnar cells, and have two fine processes, the outer or distal one passing into a dentine tubule; the inner being continuous with the processes of the connective-tissue cells of the pulp-matrix.

According to some anatomists, the processes of the odontoblasts are also continued into the dentine tubuli.

The solid portion of the tooth consists of three distinct structures—viz. the proper dental substance, which forms the larger portion of the tooth, the *ivory* or *dentine*; a layer which covers the exposed part of the crown, the *enamel*; and a thin layer, which is disposed on the surface of the fang, the *cement* or *crusta petrosa*.

The *ivory*, or *dentine* (Fig. 513), forms the principal mass of a tooth; in its central part is the cavity enclosing the pulp. It is a modification of osseous tissue, from which it differs, however, in structure. On microscopic examination it is seen to consist of a number of minute wavy and branching tubes having distinct parietes. They are called the *dental tubuli*, and are imbedded in a dense homogeneous substance, the *intertubular tissue*.

The *dental tubuli* (Fig. 514) are placed parallel with one another, and open at their inner ends into the pulp-cavity. In their course to the periphery they present two or three curves, and are twisted on themselves in a spiral direction. The direction of these tubes varies: they are vertical in the upper portion of the crown, oblique in the neck and upper part of the root, and toward the lower part of the

FIG. 512.—Vertical section of a molar tooth.

FIG. 513.—Vertical section of a bicuspid tooth. (Magnified.)

FIG. 514.—Canine tooth of man, presenting a transverse section of a portion of the root. (Magnified 300 diameters.)

root they are inclined downward. The tubuli, at their commencement, are about $\frac{1}{45000}$ of an inch in diameter; in their course they divide and subdivide dichotomously, so as to give to the cut surface of the dentine a striated appearance. From the sides of the tubes, especially in the fang, ramifications of extreme minuteness are given off, which join together in loops in the intertubular substance, or terminate in small dilatations, from which branches are given off. Near the periphery of the dentine the finer ramifications of the tubuli terminate in a layer of irregular branched spaces which communicate with each other.

These are called the *interglobular spaces of Czermak*, or the *granular layer of Purkinje* (Fig. 514). The dental tubuli have comparatively thick walls, and contain slender cylindrical prolongations from the cells of the pulp-tissue, first described by Mr. Tomes, and named Tomes's fibres or dentinal fibres. These dentinal fibres are analogous to the soft contents of the canaliculi of bone. Between Tomes's fibres and the ivory of the canals there is an elastic homogeneous membrane which resists the action of acids—the *dentinal sheath of Neumann*.

The *intertubular substance* is translucent, finely granular, and contains the chief part of the earthy matter of the dentine. After the earthy matter has been removed by steeping a tooth in weak acid the animal basis remaining may be torn into laminae which run parallel with the pulp-cavity across the direction of the tubes. A section of dentine often displays a series of somewhat parallel lines—the *incremental lines of Salter*. These lines are composed of a number of masses of imperfectly calcified dentine arranged in layers. In consequence of the imperfection in the calcifying process little irregular cavities are left, termed *interglobular spaces*, similar to those in the granular layer, but larger. They have received their name from the fact that they are surrounded by minute nodules or globules of dentine. Other curved lines may be seen parallel to the surface. These are the *lines of Schreger*, and are due to the optical effect of simultaneous curvature of the dentinal fibres.

Chemical Composition.—According to Berzelius and Bibra, dentine consists of 28 parts of animal and 72 of earthy matter. The animal matter is resolvable by boiling into gelatin. The earthy matter consists of phosphate of lime, carbonate of lime, a trace of fluoride of calcium, phosphate of magnesia, and other salts.

The **enamel** is the hardest and most compact part of a tooth, and forms a thin crust over the exposed part of the crown as far as the commencement of the fang. It is thickest on the grinding surface of the crown until worn away by attrition, and becomes thinner toward the neck. It consists of a congeries of minute hexagonal rods. They lie parallel with one another, resting by one extremity upon the dentine, which presents a number of minute depressions for their reception, and forming the free surface of the crown by the other extremity. These fibres are directed vertically on the summit of the crown, horizontally at the sides; they are about the $\frac{1}{3500}$ of an inch in diameter, and pursue a more or less wavy course. The enamel is marked by a series of undulating lines, which cross each other, or "decussate;" these lines are doubtless formed by the variation in the course of the enamel-rods. Another series of lines, having a brown appearance, and denominated the *parallel striae of Retzius*, are seen on a section of the enamel. Their exact significance is uncertain.

Numerous minute interstices intervene between the enamel-fibres near their dentinal surface, a provision calculated to allow of the permeation of fluids from the dentinal tubule into the substance of the enamel. It is a disputed point whether the dentinal fibres penetrate a certain distance between the rods of the enamel or not. No nutritive canals exist in the enamel.

Chemical Composition.—According to Bibra, enamel consists of 96.5 per cent. of earthy matter and 3.5 per cent. of animal matter. The earthy matter consists of phosphate of lime, with traces of fluoride of calcium, carbonate of lime, phosphate of magnesia, and other salts.

The **cortical substance**, or *cement (crusta petrosa)*, is disposed as a thin layer on the roots of the teeth, from the termination of the enamel as far as the apex of the fang, where it is usually very thick. In structure and chemical composition it resembles bone. It contains, sparingly, the lacunæ and canaliculi which characterize true bone; the lacunæ placed near the surface have the canaliculi radiating from the side of the lacunæ toward the periodontal membrane, and those more deeply placed join with the adjacent dental tubuli. In the thicker portions of the *crusta petrosa* the lamellæ and Haversian canals peculiar to bone are also found.

As age advances the cement increases in thickness, and gives rise to those bony growths, or exostoses, so common in the teeth of the aged; the pulp-cavity becomes also partially filled up by a hard substance intermediate in structure between dentine and bone (*osteo-dentine*, Owen; *secondary dentine*, Tomes). It appears to be formed by a slow conversion of the dental pulp, which shrinks or even disappears.

Development of the Teeth.

In describing the development of the teeth we have first to consider the mode of formation of the temporary or milk teeth, and then that of the permanent series.

Development of the Temporary Teeth.—The development of these teeth in the fœtus begins at a very early period. About the seventh week the margin of the jaw presents a slight longitudinal depression or groove with rounded borders. This is termed the *primitive dental groove of Goodsir*, and is caused by an involution of the epithelium of the oral cavity into the subjacent connective tissue. The projecting borders of the groove are called the *dental ridges*. The groove consists, therefore, superficially, of a collection of epithelial cells, beneath which is a gelatinous connective tissue, which is taken to represent the corium and connective tissue of the mucous membrane; and deeper than this is the ossifying substance of the jaw. The essential structures of the teeth are derived from these elements—the enamel from the epithelium which covers the surface of the dental groove; the dentine and crusta petrosa from the deeper structures.

First, as to the enamel. The primitive dental groove increases in size by the growing up of the corium in front and behind, and is filled up and covered in by the epithelium, which becomes greatly increased in quantity, so that the groove is only indicated by a shallow superficial furrow. Secondary ridges of corium rise at intervals along the floor of the groove, dividing it into a series of pits. As the dental ridges—that is to say, the sides of the groove—rise up, epithelial masses are contained within the separate pits; these are called *enamel-germs*, and seem to pass deeper and deeper into the substance of the jaw, and at last meet with the papillæ, presently to be described. The lower part of these masses of epithelial cells—that is, the part farthest from the margin of the jaw—spreads out in all directions, and the epithelial cells here increase in number. Each mass thus assumes a flask shape, which is connected by a narrow neck, embraced by the dental ridges, with the epithelial lining of the mouth. It may now be compared to a tubular gland, consisting of a dilated extremity filled with epithelium and opening by a narrow duct, also filled with epithelium, on the margin of the jaw. This narrow, constricted portion is called the *neck of the enamel-organ*, and is of importance as being the part from which the enamel-organ of the future permanent tooth is derived. The lower expanded portion of the mass of epithelial cells, the body of the flask, now inclines outward, so as to form an angle with the neck or more superficial part.

In the soft connective tissue beneath this mass of epithelial cells small papillæ, corresponding in number to the pits in the primitive dental groove, arise by an increased development and growth of the corpuscles of the part. They grow upward, become vascular, and come in contact with the epithelial cells of the enamel-germ, and are received into dimples on its under surface. By continued growth they push their way up into the enamel-germs, which become folded over them like a hood or cap. We have then, at this stage, vascular papillæ which have already begun to assume somewhat the shape of the crowns of the future teeth, surmounted by domes or caps of epithelial cells, which were originally the cells contained in the lower or expanded part of the flask-shaped masses in the primitive dental groove (Fig. 515). These cells now undergo a differentiation into three classes or varieties. Those which are in contact with the papilla, and which are continuous through the neck of the enamel-germ with the deepest layer of cells of the oral epithelium, become elongated and form a layer of well-marked and regular columnar epithelium coating the papilla. These are named the

internal enamel epithelium. The outer layer of cells of the enamel-germ, which are in contact with the inner surface of the dentinal sac, presently to be described, are much shorter, cubical in form, and are named the *external enamel epithelium*. All the intermediate round cells of the enamel-germ between these two layers undergo a peculiar change. They become stellate in shape, and their processes unite to form a network which resembles gelatinous connective tissue.

While these changes have been going on the soft embryonic tissue from which the papillæ arose, and which is situated beneath the enamel-germs, grows upward in the form of ridges, surrounding the rudimentary teeth and becoming converted into a vascular membrane, constituting a sac—the *dentinal sac*—which encloses each tooth. As they grow upward the two ridges approach one another, and, penetrating the lips of the primitive groove, they cause the neck of the enamel-organ to atrophy and disappear, so that all communication between the enamel-germ and the superficial epithelium is cut off.

FIG. 515.—Vertical section of the inferior maxilla of an early human fetus. (Magnified 25 diameters.)

We have now vascular papillæ surmounted by inverted caps or capsules of epithelial cells, the whole being surrounded by membranous sacs. The cap or capsule consists of an internal layer of cells—the internal enamel epithelium—in contact with the papilla; of an external layer of cells—the external enamel epithelium—lining the interior of the dentinal sac; and of an intermediate mass of stellate cells with anastomosing processes (Fig. 516). The enamel is formed exclusively from the internal enamel epithelium, the columnar cells of which undergo direct calcification and become elongated into the hexagonal rods of the enamel. The intermediate cells atrophy and disappear, so that the calcified internal enamel epithelium and the external enamel epithelium come into close apposition, and the cells of this latter layer form a distinct membrane, named the *cuticula dentis* or *Nasmyth's membrane*, which long remains perceptible, and, after the tooth has emerged from the gums, forms a horny layer which may be separated from the calcified mass below by the action of strong acids. It is marked by the hexagonal impressions of the enamel-prisms, and when stained by nitrate of silver shows the characteristic appearance of epithelium. It soon, however, wears away from the surface of the tooth.

Formation of the Dentine.—While these changes are taking place in the epithelium to form the enamel contemporaneous changes are occurring in the blastema or corium which result in the formation of the dentine and cement. As before stated, the first germ of the dentine consists in the formation of papillæ,

corresponding in number to the teeth, from the soft connective tissue which bounds the depressions containing the enamel-germ. The papillæ grow upward into the enamel-organ, and become coated by it and enclosed in a vascular connective tissue, the dentinal sac, in the manner above described. They then constitute the formative pulp from which the dentine and permanent pulp are derived. Each papilla consists of rounded cells, and is very vascular, and soon begins to assume the shape of the tooth which is to be developed from it. The next step is the formation of the odontoblasts, which have a relation to the development of the teeth similar to that of the osteoblasts in the formation of bone. They are formed first from the cells of the periphery of the papilla, which become enlarged and of an elongated form and provided with numerous processes. These processes as they grow become calcified externally, the calcified portion forming the walls of the dentinal tubules, and the uncalcified axial portion forming the dentinal fibres (Tomes's fibres), which are contained within the tubules. In addition to this, the lateral processes from the odontoblasts form the branches of anastomosis whereby the dentinal canals communicate. In this way the peripheral layer of the papilla becomes coated with a solid shell of dentine, on the inner surface of which a second layer of odontoblasts is arranged, and in its turn calcifies; and thus the process goes on through the entire thickness of the dentine, the processes of one odontoblast being directly continuous with those in succeeding layers, so that each dental fibre must be regarded as formed by several continuous odontoblasts. The central part of the papilla does not undergo calcification; its cells proliferate, nerve-fibres are developed in it, and it remains persistent as the pulp of the tooth. The *cement* is formed from the wall of the dentinal sac, which is developed from the embryonic mass at the bottom of the dental groove from which the papilla originally sprang. So that the dentine and cement may be said to originate from analogous structures. In this membranous sac ossification goes on in a manner identical with the intramembranous ossification of bone, and the cement formed is simply ordinary bone containing canaliculi and lacunæ.

The germs of the milk teeth make their appearance in the following order: At the seventh week the germ of the first molar of the upper jaw appears: at the eighth week that for the canine tooth is developed; the two incisor papillæ appear about the ninth week (the central preceding the lateral); lastly, the second molar papilla is seen at the tenth week, behind the anterior molar. The teeth of the lower jaw appear rather later, the first molar papilla being only just visible at the seventh week, and the second molar papilla not being developed before the eleventh week.

Development of the Permanent Teeth.—The permanent teeth as regards their development may be divided into two sets: (1) those which replace the temporary teeth, and which, like them, are ten in number: these are the *successional permanent teeth*; and (2) those which have no temporary predecessors, but are superadded at the back of the dental series. These are three in number on either side in each jaw, and are termed the *superadded permanent teeth*. They are the three molars of the permanent set, the molars of the temporary set being replaced by the premolars or bicuspsids of the permanent set. The development of the successional

FIG. 516.—Dental sac of a human embryo at an advanced stage of development. Partly diagrammatic. *a*. Wall of the sac, formed of connective tissue, with its outer stratum *a*¹ and its inner *a*². *b*. Enamel-organ with its papillary and parietal layer of cells. *c, d*. permanent teeth—the ten anterior ones in either jaw—will be first considered. In the neck of the enamel-organ of the temporary tooth, prior to the meeting of the two dental ridges and the obliteration of this portion of the primitive dental groove, an indentation of the epithelium takes place in the layer of cells forming the posterior wall of the neck of the sac. This forms a groove or indentation similar to the groove in the oral epithelium of the margin of the jaw which formed the primitive dental groove, and from its resemblance is termed by Goodsir the *secondary dental groove*. These grooves or depressions are ten in number in each jaw, and are formed successively from before backward. They become filled with epithelial cells, and recede into the substance of the gum behind the germs of the temporary teeth. They constitute the enamel-germs of the permanent teeth. As they recede they become flask-shaped, from an expansion of their distal extremity, and finally meet a papilla, which has been formed in the corium, just in the same manner as was the case in the temporary teeth. The apex of the papilla indentates the enamel-germ, which encloses it, and forming a cap for it, undergoes analogous changes to those described in the development of the milk teeth, and becomes converted into the enamel, whilst the papilla forms the dentine of the permanent tooth. In its development it becomes enclosed in a dental sac which adheres to the back of the sac of the temporary tooth. The sac of each permanent tooth remains connected with the fibrous tissue of the gum by a slender band or *gubernaculum*, which passes to the margin of the jaw behind the corresponding milk tooth.

The *superadded permanent teeth*—three on each side in each jaw—arise from successive extensions backward of the back part of the enamel-germ of the immediately preceding tooth. During the fourth month that portion of the enamel-germ of the last temporary molar tooth which lies behind the tooth, and which has remained unaltered, is prolonged backward and forms the enamel-germ of the first permanent molar into which a papilla projects. From this tooth, in a similar manner, about the seventh month after birth the second molar is formed, and about the third year the third molar is formed by an extension backward of the enamel-germ of the second molar.

Eruption.—When the calcification of the different tissues of the tooth is sufficiently advanced to enable it to bear the pressure to which it will be afterward subjected, its eruption takes place, the tooth making its way through the gum. The gum is absorbed by the pressure of the crown of the tooth against it, which is itself pressed up by the increasing size of the fang. At the same time the septa between the dental sacs, at first fibrous in structure, ossify, and constitute the alveoli; these firmly embrace the necks of the teeth and afford them a solid basis of support.

The eruption of the temporary teeth commences at the seventh month, and is complete about the end of the second year, those of the lower jaw preceding the upper.

The periods for the eruption of the temporary set are—

7th month, central incisors.	12th to 14th month, anterior molars.
7th to 10th month, lateral incisors.	14th to 20th month, canine.
18th to 36th month, posterior molars.	

Calcification of the permanent teeth commences a little before birth, and proceeds in the following order in the upper jaw—in the lower jaw a little earlier: First molar, fifth or sixth month; the central incisor, a little later; lateral incisors and canine, about the eighth or ninth month; the bicuspid at the second year; second molar, fifth or sixth year; wisdom tooth about the twelfth year.

Previous to the permanent teeth penetrating the gum the bony partitions which separate their sacs from the deciduous teeth are absorbed, the fangs of the temporary teeth disappear by absorption through the agency of particular multinucleated cells, called *odontoclasts*, which are developed at the time in the neighborhood of the fang, and the permanent teeth become placed under the loose crowns of the

deciduous teeth; the latter finally become detached, and the permanent teeth take their place in the mouth.

The eruption of the permanent teeth takes place at the following periods, the teeth of the lower jaw preceding those of the upper by a short interval:

6½ years, first molars.	10th year, second bicuspid.
7th year, two middle incisors.	11th to 12th year, canine.
8th year, two lateral incisors.	12th to 13th year, second molars.
9th year, first bicuspid.	17th to 21st year, wisdom teeth.

THE PALATE.

The **palate** forms the roof of the mouth: it consists of two portions, the hard palate in front, the soft palate behind.

The **hard palate** is bounded in front and at the sides by the alveolar arches and gums; behind, it is continuous with the soft palate. It is covered by a dense structure formed by the periosteum and mucous membrane of the mouth, which are intimately adherent together. Along the middle line is a linear ridge or raphe, which terminates anteriorly in a small papilla corresponding with the inferior opening of the anterior palatine fossa. This papilla receives filaments from the naso-palatine and anterior palatine nerves. On either side and in front of the raphe the mucous membrane is thick, pale in color, and corrugated; behind, it is thin, smooth, and of a deeper color: it is covered with squamous epithelium, and furnished with numerous glands (palatal glands), which lie between the mucous membrane and the surface of the bone.

The **soft palate** (*velum pendulum palati*) is a movable fold suspended from the posterior border of the hard palate, and forming an incomplete septum between the mouth and pharynx. It consists of a fold of mucous membrane enclosing muscular fibres, an aponeurosis, vessels, nerves, adenoid tissue, and mucous glands. When occupying its usual position (*i. e.* relaxed and pendent) its anterior surface is concave, continuous with the roof of the mouth, and marked by a median ridge or raphe, which indicates its original separation into two lateral halves. Its posterior surface is convex, and continuous with the mucous membrane covering the floor of the posterior nares. Its upper border is attached to the posterior margin of the hard palate, and its sides are blended with the pharynx. Its lower border is free.

Hanging from the middle of its lower border is a small, conical-shaped pendulous process, the *uvula*, and arching outward and downward from the base of the uvula on each side are two curved folds of mucous membrane, containing muscular fibres, called the *arches* or *pillars of the soft palate*.

The *anterior pillars* run downward, outward, and forward to the sides of the base of the tongue, and are formed by the projection of the Palato-glossi muscles, covered by mucous membrane.

The *posterior pillars* are nearer to each other and larger than the anterior; they run downward, outward, and backward to the sides of the pharynx, and are formed by the projection of the Palato-pharyngei muscles, covered by mucous membrane. The anterior and posterior pillars are separated below by a triangular interval in which the tonsil is lodged.

The space left between the arches of the palate on the two sides is called the *isthmus of the fauces*. It is bounded, above, by the free margin of the soft palate; below, by the back of the tongue; and on each side, by the pillars of the soft palate and the tonsil.

The *mucous membrane of the soft palate* is thin, and covered with squamous epithelium on both surfaces, excepting near the orifice of the Eustachian tube, where it is columnar and ciliated.¹ Beneath the mucous membrane on the oral surface

¹ According to Klein, the mucous membrane on the nasal surface of the soft palate is in the fetus covered throughout by columnar ciliated epithelium.

of the soft palate is a considerable amount of adenoid tissue. The palatine glands form a continuous layer on its posterior surface and round the uvula.

The *aponeurosis of the soft palate* is a thin but firm fibrous layer attached above to the posterior border of the hard palate, and becoming thinner toward the free margin of the velum. Laterally, it is continuous with the pharyngeal aponeurosis. It forms the framework of the soft palate, and is joined by the tendon of the Tensor palati muscle.

The *muscles of the soft palate* are five on each side: the Levator palati, Tensor palati, Azygos uvulæ, Palato-glossus, and Palato-pharyngeus (see page 423). The following is the relative position of these structures in a dissection of the soft palate from the posterior or nasal to the anterior or oral surface: Immediately beneath the nasal mucous membrane is a thin stratum of muscular fibres, the posterior fasciculus of the Palato-pharyngeus muscle, joining with its fellow of the opposite side in the middle line. Beneath this is the Azygos uvulæ, consisting of two rounded fleshy fasciculi, placed side by side in the median line of the soft palate. Next comes the aponeurosis of the Levator palati, joining with the muscle of the opposite side in the middle line. Fourthly, the anterior fasciculus of the Palato-pharyngeus, thicker than the posterior, and separating the Levator palati from the next muscle, the Tensor palati. This muscle terminates in a tendon which, after winding round the hamular process, expands into a broad aponeurosis in the soft palate, anterior to the other muscles which have been enumerated. Finally, we have a thin muscular stratum, the Palato-glossus muscle, placed in front of the aponeurosis of the Tensor palati, and separated from the oral mucous membrane by adenoid tissue.

The *tonsils (amygdalæ)* are two glandular organs, situated one on each side of the fauces, between the anterior and posterior pillars of the soft palate. They are of a rounded form, and vary considerably in size in different individuals. Externally the tonsil is in relation with the inner surface of the Superior constrictor, which separates it from the internal carotid and ascending pharyngeal arteries. It corresponds to the angle of the lower jaw. Its *inner surface* presents from twelve to fifteen orifices, leading into small recesses, from which numerous follicles branch out into the substance of the gland. These follicles are lined by a continuation of the mucous membrane of the pharynx, covered with epithelium; around each follicle is a layer of closed capsules imbedded in the submucous tissue. These capsules are analogous to those of Peyer's glands, consisting of adenoid tissue. No openings from the capsules into the follicles can be recognized. They contain a thick grayish secretion. Surrounding each follicle is a close plexus of lymphatic vessels. From these plexuses the lymphatic vessels pass to the deep cervical glands in the upper part of the neck, which frequently become enlarged in affections of these organs.

The *arteries* supplying the tonsil are the dorsalis lingule from the lingual, the ascending palatine and tonsillar from the facial, the ascending pharyngeal from the external carotid, the descending palatine branch of the internal maxillary, and a twig from the small meningeal.

The *veins* terminate in the tonsillar plexus, on the outer side of the tonsil.

The *nerves* are derived from Meckel's ganglion and from the glosso-pharyngeal.

THE SALIVARY GLANDS (Fig. 517).

The principal salivary glands communicating with the mouth and pouring their secretion into its cavity are the parotid, submaxillary, and sublingual.

The *parotid gland*, so called from being placed near the ear (*παρά*, near; *οὖς*, *ωτόν*, the ear), is the largest of the three salivary glands, varying in weight from half an ounce to an ounce. It lies upon the side of the face immediately below and in front of the external ear. It is limited above by the zygoma; below, by the angle of the jaw and by a line drawn between it and the mastoid process; anteriorly, it extends to a variable extent over the Masseter muscle; posteriorly,

it is bounded by the external meatus, the mastoid process, and the Sterno-mastoid and Digastric muscles, slightly overlapping the latter.

Its *anterior surface* is grooved to embrace the posterior margin of the ramus of the lower jaw, and advances forward beneath the ramus, between the two Pterygoid muscles and in front of the ramus over the Masseter muscle. Its *outer surface*, slightly lobulated, is covered by the integument and parotid fascia, and has one or two lymphatic glands resting on it. Its *inner surface* extends deeply into the neck by means of two large processes, one of which dips behind the styloid process and projects beneath the mastoid process and the Sterno-mastoid muscle; the other is situated in front of the styloid process, and passes into the back part of the glenoid fossa, behind the articulation of the lower jaw. The structures passing through the parotid gland are—the external carotid artery, giving off its three terminal branches: the posterior auricular artery emerges from the gland behind; the temporal artery above; the transverse facial, a branch of the temporal, in front;

FIG. 517.—The salivary glands.

and the internal maxillary winds through it as it passes inward, behind the neck of the jaw. Superficial to the external carotid is the trunk formed by the union of the temporal and internal maxillary veins; a branch, connecting this trunk with the internal jugular, also passes through the gland. It is also traversed by the facial nerve and its branches, which emerge at its anterior border; branches of the great auricular nerve pierce the gland to join the facial, and the auriculo-temporal branch of the inferior maxillary nerve emerges from the upper part of the gland. The internal carotid artery and internal jugular vein lie close to its deep surface.

The duct of the parotid gland (*Stenson's*) is about two inches and a half in length. It commences by numerous branches from the anterior part of the gland, crosses the Masseter muscle, and at its anterior border dips down into the substance of the Buccinator muscle, which it pierces; it then runs for a short distance obliquely forward between the Buccinator and mucous membrane of the mouth, and opens upon the inner surface of the cheek by a small orifice opposite the second molar

tooth of the upper jaw. While crossing the Masseter it receives the duct of a small detached portion of the gland, *socia parotidis*, which occasionally exists as a separate lobe, just beneath the zygomatic arch. In this position it has the transverse facial artery above it and some branches of the facial nerve below it.

Structure.—The parotid duct is dense, of considerable thickness, and its canal about the size of a crowquill; it consists of an external or fibrous coat, of considerable density, containing contractile fibres, and of an internal or mucous coat lined with short columnar epithelium.

Surface Form.—The direction of the duct corresponds to a line drawn across the face about a finger's breadth below the zygoma; that is, from the lower part of the tragus to midway between the free margin of the upper lip and the ala of the nose.

Vessels and Nerves.—The *arteries* supplying the parotid gland are derived from the external carotid, and from the branches given off by that vessel in or near its substance. The *veins* empty themselves into the external jugular through some of its tributaries. The *lymphatics* terminate in the superficial and deep cervical

FIG. 518.—A highly magnified section of the submaxillary gland of the dog, stained with carmine. (Kölliker.)

glands, passing in their course through two or three lymphatic glands placed on the surface and in the substance of the parotid. The *nerves* are derived from the carotid plexus of the sympathetic, the facial, the auriculo-temporal, and great auricular nerves.

It is probable that the branch from the auriculo-temporal nerve is derived from the glosso-pharyngeal through the otic ganglion (see page 770). At all events, in some of the lower animals this has been proved experimentally to be the case.

The **submaxillary gland** is situated below the jaw, in the anterior part of the submaxillary triangle of the neck. It is irregular in form and weighs about two drachms. It is covered by the integument, Platysma, deep cervical fascia, and the body of the lower jaw, corresponding to a depression on the inner surface of that bone, and lies upon the Mylo-hyoid, Hyo-glossus, and Stylo-glossus muscles, a portion of the gland passing beneath the posterior border of the Mylo-hyoid. In front of it is the anterior belly of the Digastric; behind, it is separated from the parotid gland by the stylo-maxillary ligament, and from the sublingual gland in front by the Mylo-hyoid muscle. The facial artery lies imbedded in a groove in its posterior and upper border.

The **duct of the submaxillary gland** (*Wharton's*) is about two inches in length, and its walls are much thinner than those of the parotid duct. It commences by numerous branches from the deep portion of the gland, and passes forward and inward between the Mylo-hyoid and the Hyo-glossus and Genio-hyo-glossus muscles, then between the sublingual gland and the Genio-hyo-glossus, and opens by a narrow orifice on the summit of a small papilla at the side of the frenum linguae. On the Hyo-glossus muscle it lies between the lingual and hypoglossal nerves, but

at the anterior border of the muscle it crosses under the lingual nerve, and is then placed above it.

Vessels and Nerves.—The *arteries* supplying the submaxillary gland are branches of the facial and lingual. Its *veins* follow the course of the arteries. The *nerves* are derived from the submaxillary ganglion, through which it receives filaments from the chorda tympani of the facial and lingual branch of the inferior maxillary, from the mylo-hyoid branch of the inferior dental, and from the sympathetic.

The **sublingual gland** is the smallest of the salivary glands. It is situated beneath the mucous membrane of the floor of the mouth, at the side of the frænum linguae, in contact with the inner surface of the lower jaw, close to the symphysis. It is narrow, flattened, in shape somewhat like an almond, and weighs about a drachm. It is in relation, *above*, with the mucous membrane; *below*, with the Mylo-hyoid muscle; *in front*, with the depression on the side of the symphysis of the lower jaw, and with its fellow of the opposite side; *behind*, with the deep part of the submaxillary gland; and *internally*, with the Genio-hyo-glossus, from which it is separated by the lingual nerve and Wharton's duct. Its excretory ducts (*ducts of Rivini*), from eight to twenty in number, open separately into the mouth, on the elevated crest of mucous membrane caused by the projection of the gland, on either side of the frænum linguae. One or more join to form a tube which opens into the Whartonian duct; this is called the *duct of Bartholin*.

Vessels and Nerves.—The sublingual gland is supplied with blood from the sublingual and submental arteries. Its nerves are derived from the lingual.

Structure of Salivary Glands.—The salivary are compound racemose glands, consisting of numerous lobes, which are made up of smaller lobules connected together by dense areolar tissue, vessels, and ducts. Each lobule consists of the ramifications of a single duct, "branching frequently in a tree-like manner," the branches terminating in dilated ends or alveoli, on which the capillaries are distributed. These alveoli, however, as Pflüger points out, are not necessarily spherical, though sometimes they assume that form; sometimes they are perfectly cylindrical, and very often they are mutually compressed. The alveoli are enclosed by a basement membrane which is continuous with the membrana propria of the duct. It presents a peculiar reticulated structure, having the appearance of a basket with open meshes, and consisting of a network of branched and flattened nucleated cells.

The alveoli of the salivary glands are of two kinds, which differ both in the appearance of their secreting cells, in their size, and in the nature of their secretion. The one variety secretes a ropy fluid which contains mucin, and has therefore been named the *mucous*, whilst the other secretes a thinner and more watery fluid, which contains serum-albumin, and has been named *serous* or *albuminous*. The sublingual gland may be regarded as an example of the former variety, the parotid of the latter. The submaxillary is of the mixed variety, containing both mucous and serous alveoli, the latter, however, preponderating.

Both alveoli are lined by cells, and it is by the character of these cells that the nature of the gland is chiefly to be determined. In addition, however, the alveoli of the serous glands are smaller than those of the mucous ones.

The **cells in the mucous alveoli** are spheroidal in shape, glassy, transparent, and dimly striated in appearance. The nucleus is usually situated in the part of the cell which is next the basement membrane, against which it is sometimes flattened. The most remarkable peculiarity presented by these cells is, that they give off an extremely fine process, which is curved in a direction parallel to the surface of the alveolus, lies in contact with the membrana propria, and overlaps the process of neighboring cells. The cells contain a quantity of mucin, to which their clear, transparent appearance is due.

Here and there in the alveoli are seen peculiar half-moon-shaped bodies lying

between the cells and the membrana propria of the alveolus. They are termed the *crescents of Gianuzzi* or the *demi-lunes of Heidenhain* (Fig. 518), and are regarded by Pflüger as due to post-mortem change, but by most other later observers they are believed to be composed of polyhedral granular cells, which Heidenhain regards as young epithelial cells destined to supply the place of those salivary cells which have undergone disintegration. This view, however, is not accepted by Klein.

Serous Alveoli.—In the serous alveoli the cells almost completely fill the cavity, so that there is hardly any lumen perceptible. Instead of presenting the clear, transparent appearance of the cells of the mucous alveoli, they present a granular appearance, due to distinct granules of an albuminous nature imbedded in a closely-reticulated protoplasm. The ducts which originate out of the alveoli are lined at their commencement by epithelium which differs little from the pavement type. As the ducts enlarge the epithelial cells change to the columnar type, and they are described by Pflüger as attached to the basement membrane by a brush of fine hair-like processes, which he believes to be continuous with the nerve-fibres. Other anatomists regard these cells as merely striated on their deep surface. The lobules of the salivary glands are richly supplied with blood-vessels which form a dense network in the interalveolar spaces. Fine plexuses of nerves are also found in the interlobular tissue. Pflüger describes the nerves as being directly continuous with the salivary cells of the alveolus, the nerve some-

FIG. 519.—Illustrating Pflüger's views of the termination of the nerves in the alveolar cells. (From Stricker's "Handbook.") A. Direct passage of nerve into a salivary cell. B. By the medium of a multipolar ganglion cell.

times passing through a ganglion-cell just before joining the alveolus (Fig. 519, A and B). This fact has not, however, been corroborated by other observers. There is no doubt that ganglia are to be found in some salivary glands in connection with the nerve-plexuses in the interlobular tissue; thus they are to be found in the submaxillary, but not in the parotid, but whether the ultimate fibrils are connected with the salivary cells, as asserted by Pflüger, remains to be proved.

In the submaxillary and sublingual glands the lobes are larger and more loosely united than in the parotid.

Mucous Glands.—Besides the salivary glands proper, numerous other glands are found in the mouth. They appear to secrete mucus only, which serves to keep the mouth moist during the intervals of the salivary secretion, and which is mixed with that secretion in swallowing. Many of these glands are found at the posterior part of the dorsum of the tongue, behind the circumvallate papillæ, and also along its margins as far forward as the apex.¹ Others lie around and in the tonsil between its crypts, and a large number in the soft palate. These glands are of the ordinary compound racemose type.

¹ It has recently been shown by Ebner that many of these glands open into the trenches around the circumvallate papillæ, and that their secretion is more watery than that of ordinary mucous glands. He supposes that they assist in the more rapid distribution of the substance to be tasted over the region where the special apparatus of the sense of taste is situated.

Surface Form.—The orifice of the mouth is bounded by the lips, two thick, fleshy folds covered externally by integument and internally by mucous membrane, and consisting of muscles, vessels, nerves, areolar tissue, and numerous small glands. The size of the orifice of the mouth varies considerably in different individuals, but seems to bear a close relation to the size and prominence of the teeth. Its corners correspond pretty accurately to the outer border of the canine teeth. In the Mongolian tribes, where the front teeth are large and inclined forward, the mouth is large; and this, combined with the thick and everted lips which appear to be associated with prominent teeth, gives to the negro's face much of the peculiarity by which it is characterized. The smaller teeth and the slighter prominence of the alveolar arch of the more highly civilized races render the orifice of the mouth much smaller, and thus a small mouth is an indication of intelligence, and is regarded as an evidence of the higher civilization of the individual.

Upon looking into the mouth, the first thing we may note is the tongue, the upper surface of which will be seen occupying the floor of the cavity. This surface is convex, and is marked along the middle line by a raphe which divides it into two symmetrical portions. The anterior two-thirds is rough and studded with papillæ; the posterior third smooth and tuberculated, covered by numerous glands which project from the surface. Upon raising the tongue the mucous membrane which invests the upper surface may be traced covering the sides of the under surface, and then reflected over the floor of the mouth on to the inner surface of the lower jaw, a part of which it covers. As it passes over the borders of the tongue it changes its character, becoming thin and smooth and losing the papillæ which are to be seen on the upper surface. In the middle line the mucous membrane on the under surface of the tip of the tongue forms a distinct fold, the *frænum linguae*, by which this organ is connected to the symphysis of the jaw. Occasionally it is found that this frænum is rather shorter than natural, and, acting as a bridle, prevents the complete protrusion of the tongue. When this condition exists and an attempt is made to protrude the organ, the tip will be seen to remain buried in the floor of the mouth, and the dorsum of the tongue is rendered very convex, and more or less extruded from the mouth; at the same time a deep furrow will be noticed to appear in the middle line of the anterior part of the dorsum. Sometimes, a little external to the frænum, the ranine vein may be seen immediately beneath the mucous membrane. The corresponding artery, being more deeply placed, does not come into view, nor can its pulsation be felt with the finger. On either side of the frænum, in the floor of the mouth, is a longitudinal elevation or ridge, produced by the projection of the sublingual gland, which lies immediately beneath the mucous membrane. And close to the attachment of the frænum to the tip of the tongue may be seen on either side the slit-like orifices of Wharton's ducts, into which a fine probe may be passed without much difficulty. By everting the lips the smooth mucous membrane lining them may be examined, and may be traced from them on to the outer surface of the alveolar arch. In the middle line, both of the upper and lower lip, a small fold of mucous membrane passes from the lip to the bone, constituting the *frema*; these are not so large as the frænum linguae. By pulling outward the angle of the mouth, the mucous membrane lining the cheeks can be seen, and on it may be perceived a little papilla which marks the position of the orifice of Stenson's duct—the duct of the parotid gland. The exact position of the orifice of the duct will be found to be opposite the second molar tooth of the upper jaw. The introduction of a probe into this duct is attended with considerable difficulty. The teeth are the next objects which claim our attention upon looking into the mouth. There are, as stated above, ten in either jaw in the temporary set, and sixteen in the permanent set. The gums, in which they are implanted, are dense, firm, and vascular.

At the back of the mouth is seen the *isthmus of the fauces*, or, as it is popularly called, "the throat;" this is the space between the pillars of the fauces on either side, and is the means by which the mouth communicates with the pharynx. Above, it is bounded by the soft palate, the anterior surface of which is concave and covered with mucous membrane, which is continuous with that lining the roof of the mouth. Projecting from the middle of its lower border is a conical-shaped projection, the *uvula*. On either side of the isthmus of the fauces are the anterior and posterior pillars, formed by the Palato-glossus and Palato-pharyngeus muscles respectively, covered over by mucous membrane. Between the two pillars on either side is situated the tonsil. By their external surface these glands are in close relationship with the internal carotid artery, being separated from this vessel only by the thin plane of muscular fibres forming the wall of the pharynx. It is stated that this vessel may be wounded in removing the tonsil. The extirpation of this glandular body is not unattended with danger of hæmorrhage from other sources. Dr. Weir has stated that he believes that when hæmorrhage occurs after their removal it arises from one of the palatine arteries having been wounded. These vessels are large; they lie in the muscular tissue of the palate, and when wounded are constantly exposed to disturbance from the contraction of the palatine muscles. The vessels of the tonsil, Dr. Weir states, are small and lie in the soft tissue, and readily contract when wounded.

When the mouth is wide open a prominent tense fold of mucous membrane may be seen and felt, extending upward and backward from the position of the fang of the last molar tooth to the posterior part of the hard palate. This is caused by the Pterygo-maxillary ligament, which is attached by one extremity to the apex of the internal pterygoid plate, and by the other to the posterior extremity of the mylo-hyoid ridge of the lower jaw. It connects the Buccinator with the Superior constrictor of the pharynx. The fang of the last molar tooth indicates

the position of the lingual (gustatory) nerve, where it is easily accessible, and can with readiness be divided in cases of cancer of the tongue (see page 772). On the inner side of the last molar tooth we can feel the hamular process of the internal pterygoid plate of the sphenoid bone, around which the tendon of the Tensor palati plays. The exact position of this process is of importance in performing the operation of staphylorrhaphy. About one-third of an inch in front of the hamular process, and the same distance directly inward from the last molar tooth, is the situation of the opening of the posterior palatine canal, through which emerges the posterior or descending palatine branch of the internal maxillary artery and one of the descending palatine nerves from Meckel's ganglion. The exact position of the opening on the subject may be ascertained by driving a needle through the tissues of the palate in this situation, when it will be at once felt to enter the canal. The artery emerging from the opening runs forward in a groove in the bone just internal to the alveolar border of the hard palate, and may be wounded in the operation for the cure of cleft palate. Under these circumstances the palatine canal may require plugging. By introducing the finger into the mouth the anterior border of the coronoid process of the jaw can be felt, and is especially prominent when the jaw is dislocated. By throwing the head well back a considerable portion of the posterior wall of the pharynx may be seen through the isthmus faucium, and on introducing the finger the anterior surface of the bodies of the upper cervical vertebræ may be felt immediately beneath the thin muscular stratum forming the wall of the pharynx. The finger can be hooked around the posterior border of the soft palate, and by turning it forward the posterior nares, separated by the septum, can be felt, or the presence of any adenoid or other growths in the naso-pharynx ascertained.

THE PHARYNX.

The **pharynx** is that part of the alimentary canal which is placed behind the nose, mouth, and larynx. It is a musculo-membranous sac, somewhat conical in form, with the base upward and the apex downward, extending from the under surface of the skull to the cricoid cartilage in front and the intervertebral disk between the fifth and sixth cervical vertebræ behind.

The pharynx is about four inches and a half in length, and broader in the transverse than in the antero-posterior diameter. Its greatest breadth is opposite the cornua of the hyoid bone; its narrowest point, at its termination in the œsophagus. It is limited, *above*, by the body of the sphenoid and basilar process of the occipital bone; *below*, it is continuous with the œsophagus; *posteriorly*, it is connected by loose areolar tissue with the cervical portion of the vertebral column and the Longi colli and Recti capitis antici muscles; *anteriorly*, it is incomplete, and is attached in succession to the internal pterygoid plate, the pterygo-maxillary ligament, the lower jaw, the tongue, hyoid bone, and thyroid and cricoid cartilages; *laterally*, it is connected to the styloid processes and their muscles, and is in contact with the common and internal carotid arteries, the internal jugular veins, and the glosso-pharyngeal, pneumogastric, hypoglossal, and sympathetic nerves, and above with a small part of the Internal pterygoid muscles.

It has seven openings communicating with it—the two posterior nares, the two Eustachian tubes, the mouth, larynx, and œsophagus.

The *posterior nares* are the two oval openings (see page 224) situated at the upper part of the anterior wall of the pharynx.

The *two Eustachian tubes* open one at each side of the upper part of the pharynx, at the back part of the inferior meatus. Below the posterior nares are the posterior surface of the soft palate and uvula, the large aperture of the mouth, the base of the tongue, the epiglottis, and the cordiform opening of the larynx.

The *œsophageal opening* is the lower contracted portion of the pharynx.

Structure.—The pharynx is composed of three coats—mucous, fibrous, and muscular.

The *pharyngeal aponeurosis*, or *fibrous coat*, is situated between the mucous and muscular layers. It is thick above, where the muscular fibres are wanting, and is firmly connected to the basilar process of the occipital and petrous portion of the temporal bones. As it descends it diminishes in thickness, and is gradually lost. It is strengthened posteriorly by a strong fibrous band which is attached above to the pharyngeal spine on the under surface of the basilar portion of the occipital bone, and passes downward, forming a median raphe, which gives attachment to the Constrictor muscles of the pharynx.

The *mucous coat* is continuous with that lining the Eustachian tubes, the nares, the mouth, and the larynx. It is covered by columnar ciliated epithelium, as low down as on a level with the floor of the nares; below that point the epithelium is of the squamous variety. Beneath the mucous membrane are found racemose mucous glands; they are especially numerous at the upper part of the pharynx around the orifices of the Eustachian tubes. Throughout the pharynx are also numerous crypts or recesses, the walls of which are surrounded by lymphoid tissue similar to what is found in the tonsils. Across the back part of the pharyngeal cavity, between the two Eustachian tubes, a considerable mass of this tissue exists, and has been named the *pharyngeal tonsil*. Above this in the middle line is an irregular, flask-shaped depression of the mucous membrane, extending up as far as the basilar process of the occipital bone. It is known as the *bursa pharyngea*, and is the remains of the diverticulum of the alimentary canal, which is concerned in the development of the pituitary body (see page 121).

The *muscular coat* has been already described (page 421).

Surgical Anatomy.—The internal carotid artery is in close relation with the pharynx, so that its pulsations can be felt through the mouth. It has been occasionally wounded by sharp-pointed instruments introduced into the mouth and thrust through the wall of the pharynx. In aneurism of this vessel in the neck the tumor necessarily bulges into the pharynx, as this is the direction in which it meets with the least resistance, nothing lying between the vessel and the mucous membrane except the thin Constrictor muscle, whereas on the outer side there is the dense cervical fascia, the muscles descending from the styloid process, and the margin of the Sterno-mastoid.

The mucous membrane of the pharynx is very vascular, and is often the seat of inflammation, frequently of a septic character, and dangerous on account of its tendency to spread to the larynx. On account of the tissue which surrounds the pharyngeal wall being loose and lax, the inflammation is liable to spread through it far and wide, extending downward into the posterior mediastinum along the œsophagus. Abscess may form in the connective tissue behind the pharynx, between it and the vertebral column, constituting what is known as post-pharyngeal abscess. This is most commonly due to caries of the cervical vertebrae, but may also be caused by suppuration of a lymphatic gland which is situated in this position opposite the axis, and which receives lymphatics from the nares, or by a gumma or by acute pharyngitis. The abscess may be most easily evacuated by an incision, with a guarded bistoury, through the mouth. It has recently been proposed to open the abscess aseptically by an incision in the neck behind the Sterno-mastoid. The operation, however, is a difficult one, unless the abscess is pointing laterally, and does not give such free access to the seat of disease for the removal of necrosed bone, if any exists, and does not appear to present sufficient advantages to warrant its performance.

Foreign bodies not unfrequently become lodged in the pharynx, and most usually at its termination at about the level of the cricoid cartilage, just beyond the reach of the finger, as the distance from the arch of the teeth to the commencement of the œsophagus is about six inches.

The position of the opening of the Eustachian tubes should be carefully studied with a view to catheterism of these tubes, and the student should practise passing a catheter into them. This is to be done by introducing the instrument through the anterior nares, so that its point rests on the floor of the nasal cavity close to the septum: it is then pushed gradually and slowly backward until the posterior wall of the pharynx is reached. Then, having been slightly withdrawn so as to free the point from the wall of the pharynx, it is rotated outward and upward, so that the ring of the instrument is turned toward the external ear, and it can then be made to glide into the Eustachian tube.

THE ŒSOPHAGUS.

The *œsophagus*, or *gullet*, is a muscular canal, about nine inches in length, extending from the pharynx to the stomach. It commences at the upper border of the cricoid cartilage, opposite the intervertebral disk between the fifth and sixth cervical vertebrae, descends along the front of the spine through the posterior mediastinum, passes through the Diaphragm, and, entering the abdomen, terminates at the cardiac orifice of the stomach, opposite the tenth dorsal vertebra or the intervertebral disk between the tenth and eleventh dorsal vertebrae. The general direction of the œsophagus is vertical, but it presents two or three slight curves in its course. At its commencement it is placed in the median line, but it inclines to the left side as far as the root of the neck, gradually passes to the middle line again, and finally again deviates to the left as it passes forward to the œsophageal opening of the Diaphragm. The œsophagus also presents an antero-posterior

flexure, corresponding to the curvature of the cervical and thoracic portions of the spine. It is the narrowest part of the alimentary canal, being most contracted at its commencement and at the point where it passes through the Diaphragm.

Relations.—*In the neck* the œsophagus is in relation, *in front*, with the trachea, and at the lower part of the neck, where it projects to the left side, with the thyroid gland and thoracic duct; *behind*, it rests upon the vertebral column and Longi colli muscles; *on each side*, it is in relation with the common carotid artery (especially the left, as it inclines to that side) and part of the lateral lobes of the thyroid gland; the recurrent laryngeal nerves ascend between it and the trachea.

In the thorax it is at first situated a little to the left of the median line; it then passes behind the left side of the aortic arch, and descends in the posterior mediastinum, along the right side of the aorta, nearly to the Diaphragm, where it passes in front and a little to the left of the artery, previous to entering the abdomen. It is in relation, *in front*, with the trachea, the arch of the aorta, left carotid, and left subclavian arteries, the left bronchus, and the posterior surface of the pericardium; *behind*, it rests upon the vertebral column, the Longi colli muscles, and the intercostal vessels, and below, near the Diaphragm, upon the front of the aorta; *laterally*, it is covered by the pleuræ: the vena azygos major lies on the right and the descending aorta on the left side. The pneumogastric nerves descend in close contact with it, the right nerve passing down behind, and the left nerve in front of it.

Structure.—The œsophagus has three coats—an external or muscular; a middle or areolar; and an internal or mucous coat.

The *muscular coat* is composed of two planes of fibres of considerable thickness, an external longitudinal and an internal circular.

The *longitudinal fibres* are arranged, at the commencement of the tube, in three fasciculi: one in front, which is attached to the vertical ridge on the posterior surface of the cricoid cartilage; and one at each side, which is continuous with the fibres of the Inferior constrictor: as they descend they blend together and form a uniform layer, which covers the outer surface of the tube.

Accessory slips of muscular fibres are described by Dr. Cunningham as passing between the œsophagus and the pleura, where it covers the thoracic aorta (almost always), or the root of the left bronchus (usually), or the back of the pericardium or corner of the mediastinum (more rarely), as well as other still more rare accessory fibres. In Fig. 520, taken from a dissection in the Museum of the Royal College of Surgeons, several of these accessory slips may be seen passing from the œsophagus to the pleura, and two slips to the back of the trachea just above its bifurcation.

The *circular fibres* are continuous above with the Inferior constrictor; their direction is transverse at the upper and lower parts of the tube, but oblique in the central part.

The muscular fibres in the upper part of the œsophagus are of a red color, and consist chiefly of the striped variety, but below they consist for the most part of involuntary muscular fibre.

The *areolar coat* connects loosely the mucous and muscular coats.

The *mucous coat* is thick, of a reddish color above and pale below. It is disposed in longitudinal folds, which disappear on distension of the tube. Its surface is studded with minute papillæ, and it is covered throughout with a thick layer of stratified pavement epithelium. Beneath the mucous membrane, between it and the areolar coat, is a layer of longitudinally arranged non-striped muscular fibres. This is the *muscularis mucosæ*. At the commencement it is absent, or only represented by a few scattered bundles; lower down it forms a considerable stratum.

The *œsophageal glands* are numerous small compound racemose glands scattered throughout the tube; they are lodged in the submucous tissue, and open upon the surface by a long excretory duct. They are most numerous at the lower part of the tube, where they form a ring round the cardiac orifice.

Vessels of the Œsophagus.—The arteries supplying the œsophagus are derived from the inferior thyroid branch of the thyroid axis of the subclavian, from the descending thoracic aorta, and from the gastric branch of the coeliac axis from the abdominal aorta. They have for the most part a longitudinal direction.

Nerves of the Œsophagus.—The nerves are derived from the pneumogastric and from the sympathetic; they form a plexus in which are groups of ganglion-cells between the two layers of the muscular coats, and also a second plexus in the submucous tissue.

Surgical Anatomy.—The relations of the œsophagus are of considerable practical interest to the surgeon, as he is frequently required, in cases of stricture of this tube, to dilate the canal by a bougie, when it is of importance that the direction of the œsophagus and its relations to surrounding parts should be remembered. In cases of malignant disease of the œsophagus, where its tissues have become softened from infiltration of the morbid deposit, the greatest care is requisite in directing the bougie through the strictured part, as a false passage may easily be made, and the instrument may pass into the mediastinum, or into one or the other pleural cavity, or even into the pericardium.

The student should also remember that contraction of the œsophagus, and consequent symptoms of stricture, are occasionally produced by an aneurism of some part of the aorta pressing upon this tube. In such a case the passage of a bougie could only hasten the fatal issue.

In passing a bougie the left fore finger should be introduced into the mouth and the epiglottis felt for, care being taken not to throw the head too far backward. The bougie is then to be passed beyond the finger until it touches the posterior wall of the pharynx. The patient is now asked to swallow, and at the moment of swallowing the bougie is passed gently onward, all violence being carefully avoided.

It occasionally happens that a foreign body becomes impacted in the œsophagus which can neither be brought upward nor moved downward. When all ordinary means for its removal have failed, excision is the only resource. This, of course, can only be performed when it is not very low down. If the foreign body is allowed to remain, extensive inflammation and ulceration of the œsophagus may ensue. In one case the foreign body ultimately penetrated the intervertebral substance, and destroyed life by inflammation of the membranes and substance of the cord.

The operation of œsophagotomy is thus performed: The patient being placed upon his back, with the head and shoulders slightly elevated, an incision, about four inches in length, should be made on the left side of the trachea, from the thyroid cartilage downward, dividing the skin and Platysma. The edges of the wound being separated, the Omo-hyoid muscle should, if necessary, be divided, and the fibres of the Sterno-hyoid and Sterno-thyroid muscles drawn inward; the sheath of the carotid vessels, being exposed, should be drawn outward, and retained in that position by retractors: the œsophagus will now be exposed, and should be divided over the foreign body, which can then be removed. Great care is necessary to avoid wounding the thyroid vessels, the thyroid gland, and the laryngeal nerves.

The œsophagus may be obstructed not only by foreign bodies, but also by changes in its coats, producing stricture, or by pressure on it from without of new growths or aneurism, etc.

The different forms of stricture are: (1) the spasmodic, usually occurring in nervous women, and intermittent in character, so that the dysphagia is not constant; (2) fibrous, due to cicatrization after injuries, such as swallowing corrosive fluids or boiling water; and (3) malignant, usually epitheliomatous in its nature. This is situated generally either at the upper end of the tube, opposite to the cricoid cartilage, or at its lower end at the cardiac orifice, but is also occasionally found at that part of the tube where it is crossed by the left bronchus.

The operation of œsophagostomy has occasionally been performed in cases where the stricture in the œsophagus is at the upper part, with a view to making a permanent opening below the stricture through which to feed the patient, but the operation has been far from a successful one, and the risk of setting up diffuse inflammation in the loose planes of connective tissue deep in the neck is so great that it would appear to be better, if any operative interference

FIG. 520.—Accessory muscular fibres between the œsophagus and pleura, and œsophagus and trachea. (From a preparation in the Museum of the Royal College of Surgeons.)

FIG. 521.—Topography of thoracic and abdominal viscera.

is undertaken, to perform gastrostomy. The operation is performed in the same manner as œsophagotomy, but the edges of the opening in the œsophagus are stitched to the skin incision.

THE ABDOMEN.

The **Abdomen** is the largest cavity in the body. It is of an oval form, the extremities of the oval being directed upward and downward, the upper one being formed by the under surface of the Diaphragm, the lower by the upper concave surface of the Levator ani. In order to facilitate description it is artificially divided into two parts—an upper and larger part, the *abdomen proper*; and a lower and smaller part, the *pelvis*. These two cavities are not separated from each other, but the limit between them is marked by the brim of the true pelvis. The space is wider above than below, and measures more in the vertical than in the transverse diameter.

Boundaries.—The **abdomen proper** is bounded, *in front* and *at the sides*, by the lower ribs, the abdominal muscles, and the venter ilii; *behind*, by the vertebral column and the Psoas and Quadratus lumborum muscles; *above*, by the Diaphragm; *below*, by the brim of the pelvis. The muscles forming the boundaries of the cavity are lined upon their inner surface by a layer of fascia, differently named according to the part which it covers.

The abdomen contains the greater part of the alimentary canal; some of the accessory organs to digestion—viz. the liver, pancreas, and spleen; and the kidneys and suprarenal capsules. Most of these structures, as well as the wall of the cavity in which they are contained, are covered by an extensive and complicated serous membrane, the *peritoneum*.

The *apertures* found in the walls of the abdomen for the transmission of structures to or from it are—the *umbilicus*, for the transmission (in the fœtus) of the umbilical vessels; the *caval opening* in the Diaphragm, for the transmission of the inferior vena cava; the *aortic opening*, for the passage of the aorta, vena azygos, and thoracic duct; and the *œsophageal opening*, for the œsophagus and pneumogastric nerves. *Below*, there are two apertures on each side, one for the passage of the femoral vessels, and the other for the transmission of the spermatic cord in the male and the round ligament in the female.

Regions.—For convenience of description of the viscera, as well as of reference to the morbid condition of the contained parts, the abdomen is artificially divided into nine regions. Thus, if two circular lines are drawn round the body, the one through the extremities of the ninth ribs where they join their costal cartilages, and the other through the highest point of the crests of the ilia, the abdominal cavity is divided into three zones—an upper, a middle, and a lower. If two parallel lines are drawn perpendicularly upward from the centre of Poupart's ligament, each of these zones is subdivided into three parts—a middle and two lateral.

The middle region of the upper zone is called the *epigastric* (ἐπί, over; γαστήρ, the stomach); and the two lateral regions, the *right* and *left hypochondriac* (ὕπο, under; χόνδροι, the cartilages). The central region of the middle zone is the *umbilical*, and the two lateral regions, the *right* and *left lumbar*. The middle region of the lower zone is the *hypogastric* or *pubic region*, and the lateral regions are the *right* and *left inguinal* or *iliac*. The viscera contained in these different regions are the following (Fig. 522):

Right Hypochondriac.

The right lobe of the liver and the gall-bladder, hepatic flexure of the colon, and part of the right kidney.

Epigastric Region.

The pyloric end of the stomach, left lobe of the liver, and lobulus Spigelii, the pancreas, the duodenum, parts of the kidneys and the suprarenal capsules.

Left Hypochondriac.

The splenic end of the stomach, the spleen and extremity of the pancreas, the splenic flexure of the colon, and part of the left kidney.

Right Lumbar.

Ascending colon, part of the right kidney, and some convolutions of the small intestines.

Umbilical Region.

The transverse colon, part of the great omentum and mesentery, transverse part of the duodenum, and some convolutions of the jejunum and ileum, and part of both kidneys.

Left Lumbar.

Descending colon, part of the omentum, part of the left kidney, and some convolutions of the small intestines.

Right Inguinal (Iliac).

The cæcum, appendix cæci.

Hypogastric Region.

Convolutions of the small intestines, the bladder in children, and in adults if distended, and the uterus during pregnancy.

Left Inguinal (Iliac).

Sigmoid flexure of the colon.

FIG. 522.—The regions of the abdomen and their contents. (Edge of costal cartilages in dotted outline.)

THE PERITONEUM.

The **peritoneum** (*περιτонеον*, to extend around) is a serous membrane, and partially invests all the viscera contained in the abdominal and pelvic cavities. In consequence of the number and different shapes of these viscera the reflections of the peritoneum, as it invests them, are exceedingly complex and difficult to understand.

The peritoneum partially invests all the viscera contained in the abdominal and pelvic cavities, forming the visceral layer of the membrane; it is then reflected upon the internal surface of the parietes of those cavities, forming the parietal

layer. The *free surface of the peritoneum* is smooth, moist, and covered by a layer of flattened endothelial cells; its *attached surface* is rough, being connected to the viscera and inner surface of the parietes by means of areolar tissue called the *subserous areolar tissue*. The parietal portion is loosely connected with the fascia lining the abdomen and pelvis, but more closely to the under surface of the Diaphragm and in the middle line of the abdomen.

In order to get a first general idea of the peritoneum and its reflections the student should bear in mind that all the abdominal and pelvic viscera are placed external to it, and that it is a shut sac superimposed upon the viscera.¹

Let the student imagine that all the viscera are in their proper positions in the abdominal cavity, but uninvested by peritoneum. Upon the top of them is

FIG. 523.—The reflections of the peritoneum, as seen in a vertical section of the abdomen.

placed a large closed sac, the walls of which are of extreme thinness, and wherever there is a cleft between two viscera a process of peritoneum derived from the part of the sac in contact with the viscera is tucked in between them, so as to cover the adjacent surfaces of the two viscera and separate them from each other, and at the same time, by becoming adherent to the viscera, form an investment for them. Thus in Fig. 523 such a diverticulum or process may be seen tucked in between the under surface of the liver and the upper surface of the stomach, and extending between the two as far backward as the portal vein, hepatic artery, and hepatic duct, which it covers on their anterior surfaces, forming the anterior layer of what is termed the lesser omentum.

Another diverticulum or process is tucked in round the hepatic artery as it passes forward and upward to the liver, and afterward expands into a large

¹ We may disregard, for the present, the fact that the peritoneum in the female is not an absolutely closed sac, since the Fallopian tubes open into it at their free extremities.

sac or bag, which covers the posterior surface of the liver and stomach and the upper part of the posterior wall of the abdomen, separating these structures from each other. This large *cul-de-sac* of peritoneum is called the *lesser cavity of the peritoneum*, but is only a part of the general cavity, differentiated from it by the constriction produced at the situation of the hepatic artery. In this respect the peritoneum may be compared to an hour-glass with two unequal globes, the smaller one constituting the lesser cavity of the peritoneum, the larger one the greater cavity, and the constriction where the two globes communicate corresponding to the constriction in the peritoneum where it hooks round the hepatic artery. This constriction is called the foramen of Winslow.

Between the transverse fissure of the liver and the lesser curvature of the stomach there is thus a double layer of peritoneum, the anterior layer being part of the greater bag of the peritoneum, where it is tucked in between the liver and the stomach from the front, while the posterior layer is part of the lesser bag of the peritoneum where it is tucked in round the hepatic artery. These two layers constitute the lesser omentum. Between the two layers are situated the hepatic artery, the portal vein, and the hepatic duct.

A process of this lesser bag of the peritoneum is pushed backward and upward behind the liver, extending as far as the under surface of the Diaphragm, the posterior part of which it covers. At its extremity this process is in contact with a process of the greater bag of the peritoneum, which is pushed in from the front, in the cleft between the upper surface of the liver and the under surface of the Diaphragm. Where these two layers are in contact (passing down from the Diaphragm to the liver) they form some of the ligaments of the liver, thus supporting and holding it in position. Another process of this lesser bag is pushed downward between the stomach and the transverse colon, and forms the two inner of the four layers of the great omentum. Thus the lesser cavity of the peritoneum is seen to be a complete sac or bag, separating the back and part of the under surface of the liver, the posterior wall of the stomach, and the upper surface of the transverse colon from the back part of the under surface of the Diaphragm and the upper part of the posterior wall of the abdomen.

The *greater cavity of the peritoneum* separates the anterior surfaces of the viscera from the front wall of the abdomen; so that in our comparison of the two cavities to an hour-glass it must be borne in mind that they are not in the same straight line as the two globes of the hour-glass, but that at the point of constriction the smaller cavity is bent round the hepatic artery, so as to lie behind the greater cavity.

The greater sac of the peritoneum is placed in front of the viscera, one layer being in contact with them, the other lining the inner surface of the anterior wall of the abdomen. The layer which is in relation with the viscera sends backward diverticula which pass between the various organs, and in certain places comes in contact with the peritoneum forming the lesser bag, in the manner described above. Thus we have one of these diverticula sent backward between the liver and Diaphragm, covering the anterior part of the under surface of the Diaphragm, until it meets the peritoneum of the lesser cavity, and covering the upper surface of the liver as far backward as the ligaments. The extremity of this diverticulum is in contact with a similar diverticulum of the lesser bag, already described, and the two layers, when in apposition, form the coronary and lateral ligaments of the liver. Another process, which has already been mentioned, is sent backward between the under surface of the liver and the stomach to meet a similar process of the lesser cavity prolonged from behind forward. Where the two are in apposition the lesser or gastro-hepatic omentum is formed. A third diverticulum is carried backward to the posterior wall of the abdomen between the transverse colon and the small intestine. This prolongation covers the under surface of the transverse colon, and forms the under layer of the transverse meso-colon and the upper layer of the mesentery; by its extremity it is in contact with the posterior wall of the abdomen and covers a part of the abdominal aorta. Between the greater curvature

of the stomach and the transverse colon there is a fold or reduplication of the peritoneum, which contains between its layers a similar fold from the lesser cavity, and forms the apron or great omentum. Another fold of the greater bag of the peritoneum is pushed backward to the spine between the small intestines and the pelvic viscera. This fold forms the lower layer of the mesentery, covers a considerable portion of the lower part of the abdominal wall, and passes over the sacro-vertebral angle into the pelvis. Below, where it covers the upper part of the pelvic viscera, it sends diverticula *downward* between them, separating them from one another; thus one is sent downward between the back of the rectum and the sacrum, another between the rectum and the bladder. In the female one is sent down between the rectum and uterus, another between the uterus and bladder. These, then, are the various diverticula sent off from the posterior layer of the greater bag of the peritoneum; the anterior layer simply lines the anterior wall of the abdomen, and is continuous at its extremities with the posterior layer.

The student will perhaps be better able to follow these various folds or reflections of the peritoneum by a reference to the accompanying plan (Fig. 524), which should

FIG. 524.—Plan of the peritoneum.

be studied in conjunction with Fig. 523. He must not forget, however, that though the lesser and greater cavities of the peritoneum are here represented, for the sake of clearness, as quite distinct from each other, they are not really so, but that they both form part of one great cavity.

The reflections of the peritoneum may be traced in two different ways, either by considering the folds which form each cavity separately or by describing them together.

According to the first plan (Fig. 523), the liver should be raised and supported in that position, and the stomach should be depressed, when a thin membranous layer is seen passing from the transverse fissure of the liver to the upper border of the stomach: this is the *lesser* or *gastro-hepatic omentum*. It consists of two delicate layers of peritoneum, an anterior and a posterior, between which are contained the

hepatic vessels and nerves. Of these two layers, the anterior should first be traced, and then the posterior.

The *anterior layer* descends to the lesser curvature of the stomach, and covers its anterior surface as far as the great curvature: it descends for some distance in front of the small intestines, and, returning upon itself to the transverse colon, forms the *external layer of the great omentum*; it then covers the under surface of the transverse colon, and, passing to the back part of the abdominal cavity, forms the *inferior layer of the transverse meso-colon*. It then descends in front of the duodenum, the aorta, and vena cava, as far as the superior mesenteric artery, along which it passes to invest the small intestines, and, returning to the vertebral column, forms the *mesentery*; whilst on either side it covers the ascending and descending colon, and is thus continuous with the peritoneum lining the walls of the abdomen. From the root of the mesentery it descends along the front of the spine into the pelvis, and surrounds the upper part of the rectum, which it holds in its position by means of a distinct fold, the *meso-rectum*. Its course in the male and female now differs.

In the male it forms a fold between the rectum and bladder, the *recto-vesical fold*, and ascends over the posterior surface of the latter organ as far as its summit.

In the female it descends into the pelvis in front of the rectum, forms a fold between the rectum and vagina, the *recto-vaginal fold* (pouch of Douglas), covers a small part of the posterior wall of the vagina, and passes on to the uterus, the fundus and body of which it covers. From the sides of the uterus it is reflected to the wall of the pelvis, forming the broad ligaments, and from the anterior surface of the uterus it ascends upon the posterior wall of the bladder as far as its summit.

From this point it may be traced, as in the male, ascending upon the anterior parietes of the abdomen, to the under surface of the Diaphragm, from which it is reflected upon the liver, forming the upper layer of the coronary and the lateral and longitudinal ligaments. It then covers the upper and under surfaces of the liver, and at the transverse fissure becomes continuous with the anterior layer of the lesser omentum, the point whence its reflection was originally traced.

The *posterior layer of the lesser omentum* descends to the lesser curvature of the stomach, and covers its posterior surface as far as the great curvature; it then descends for some distance in front of the small intestines, and, returning upon itself to the transverse colon, forms the internal layer of the great omentum; it covers the upper surface of the transverse colon, and, passing backward to the spine, forms the upper layer of the transverse meso-colon. Ascending in front of the pancreas and crura of the Diaphragm, it lines the back part of the under surface of that muscle, from which it is reflected on to the posterior border of the liver, forming the inferior layer of the coronary ligament. From the under surface of the liver it may be traced to the transverse fissure, where it is continuous with the posterior layer of the lesser omentum, the point whence its reflection was originally traced.

The space included in the reflections of this layer of the peritoneum is called the *lesser cavity of the peritoneum*, or *cavity of the great omentum*. It is bounded, *in front*, by the lesser omentum, the stomach, and the descending part of the great omentum; *behind*, by the ascending part of the great omentum, the transverse colon, transverse meso-colon, and its ascending layer; *above*, by the liver; and *below*, by the folding of the great omentum. This space communicates with the general peritoneal cavity through the foramen of Winslow, which is situated behind the right or free border of the lesser omentum.

In order to trace the two layers together, we commence at the top of the abdominal cavity; that is to say, the under surface of the Diaphragm. This muscle is covered throughout the greater part of its extent by peritoneum, one layer extending from its anterior border backward, the other from its posterior border forward. Where the two layers meet they are reflected downward to the liver,

forming the coronary and lateral ligaments of this organ. When these two layers reach the liver, they again separate to enclose this viscus, the one passing in front and the other behind, and they meet again on its under surface at the transverse fissure. From this fissure they turn downward to the lesser curvature of the stomach, forming the gastro-hepatic or lesser omentum, and enclosing the hepatic artery, the portal vein, and the hepatic duct, which are contained between the two folds in this situation. From the lesser curvature of the stomach the two layers pass over the anterior and posterior surfaces of the viscus, enclosing it and meeting again at the greater curvature. From this point they pass down in front of the small intestines, between this tube and the abdominal wall, and are reflected on themselves, passing upward to the transverse colon, and forming the apron or great omentum. This reflection, therefore, consists of *four* layers of peritoneum. When the two posterior layers of the great omentum, in their reflection upward, reach the transverse colon, they separate to enclose this portion of the intestinal tube, the one layer passing above it and the other below. They meet on its posterior surface and pass backward to the vertebral column, forming what is called the *transverse meso-colon*. At this point the two layers separate. The one which formed the upper surface of the transverse meso-colon, and which belongs to the lesser cavity, passes upward in front of the pancreas and crura of the Diaphragm to the back part of the under surface of the Diaphragm, the point from which the description of this layer was commenced. The other, which formed the inferior layer of the transverse meso-colon, turns downward in front of the duodenum, aorta, and inferior vena cava, and can be traced, as a single layer, in the manner above described, investing the small intestines and forming the mesentery; then passing over the sacro-vertebral angle into the pelvis, the viscera of which it partially invests, and finally over the posterior surface of the front wall of the abdomen to the under surface of the Diaphragm, the point from which the description of this layer was commenced.

In addition to tracing the peritoneum vertically, as has now been done, it is necessary to trace it horizontally. If this is done below the transverse colon, the circle is extremely simple, as it includes only the greater bag of the peritoneum (Fig. 523). Above the level of the transverse colon the arrangement is more complicated, on account of the existence of two sacs.

Starting from the linea alba, below the level of the transverse colon, and tracing the continuity in a horizontal direction to the right, we find the peritoneum covering the internal surface of the abdominal wall almost as far as the anterior border of the *Quadratus lumborum* muscle; it encloses the cæcum, forming the meso-cæcum, and is reflected over the sides and anterior surface of the ascending colon, fixing it to the abdominal wall, thus forming the meso-cæcum and the ascending meso-colon, from which it can be traced over the kidney to the front of the bodies of the vertebræ. It then passes along the mesenteric vessels to invest the small intestines, and back again to the spine, forming the mesentery, between the layers of which are contained the blood-vessels, nerves, lacteals, and glands. Lastly, it passes over the left kidney to the sides and anterior surface of the descending colon, and, reaching the abdominal wall, it passes along it to the middle line of the abdomen.

Above the transverse colon (Fig. 525) the peritoneum can be traced, forming the greater and lesser cavities, and their communication through the foramen of Winslow can be demonstrated. Commencing in the middle line of the abdomen the membrane may be traced lining its anterior wall, and on the right side sending a process backward to encircle the obliterated umbilical vein (the round ligament of the liver), forming the falciform or longitudinal ligament of the liver. Continuing its course to the right, it is reflected over the front of the upper part of the right kidney, across the vena cava inferior and aorta, and over the left kidney to the hilum of the spleen. From this point it is reflected on to the posterior surface of the stomach, which it covers, and from its right extremity it passes around the vessels passing to the transverse fissure of the liver, and back again to the stomach

as the lesser omentum, and thus it forms the anterior boundary of the foramen of Winslow. It now covers the front of the stomach, and upon reaching the cardiac extremity it passes to the spleen, which it encloses, forming the gastro-splenic omentum. From the hilum of the spleen it turns backward to reach the abdominal wall, along which it courses to reach the median line of the abdomen.

The foramen of Winslow is bounded, *in front*, by the lesser omentum, enclosing

FIG. 525.—Transverse section of peritoneum. (An arrow has been introduced into the foramen of Winslow.)

the vena portæ and the hepatic artery and duct; *behind*, by the inferior vena cava; *above*, by the lobulus Spigelii and lobulus caudatus; *below*, by the hepatic artery curving forward from the celiac axis.

The reflections of the peritoneum over the transverse colon are somewhat differently described by some authors (Luschka, Holden), and there is no doubt, as was long ago pointed out by Haller, that the arrangement in the fœtus is different from that which has been described above. In the fœtus, and even in the young child, the two ascending layers of the great omentum can be traced passing together *over* the transverse colon, instead of embracing it, as described above, and passing back to the spine as a double fold, which can be separated from the transverse colon and transverse meso-colon. Upon reaching the spine the two layers separate: the upper one (the inner of the two ascending layers of the great omentum) passes upward in front of the pancreas and crura of the Diaphragm, forming the posterior boundary of the lesser bag of the peritoneum, in a similar manner to the upper layer of the transverse meso-colon in the former description. The other fold (the outer of the ascending layer of the great omentum) after reaching the spine is turned forward again on itself as far as the transverse colon, which it covers, and is again reflected back to the spine, to pass down in front of the aorta to form the mesentery, in a similar manner to the lower layer of the transverse meso-colon in the former description. Thus the transverse colon is invested by a distinct fold of peritoneum, prolonged forward from the spine to surround it, in a very similar manner to the way in which the small intestines are surrounded.

In the adult, however, as a rule, this arrangement disappears. Probably adhesion of the layers of which the foetal duplication is composed takes place, and then absorption, and thus the arrangement is brought about which has been described above as most frequently seen in the adult subject. It may be that the foetal duplicature is "drawn or pushed forward from its place in the progress of visceral development, and thus effaced."¹

Viscera covered by Peritoneum.—The viscera thus shown to be almost entirely

¹ Quain's *Anatomy*, vol. ii. p. 485, 8th ed.

invested by peritoneum are, the liver, stomach, spleen, first portion of the duodenum, the jejunum and ileum, the transverse colon, the cæcum, sigmoid flexure, upper half of the rectum, the uterus, and ovaries.

Viscera Partially covered by Peritoneum.—The viscera only partially invested by peritoneum are—the descending and transverse portions of the duodenum, the ascending and descending colon, the middle portion of the rectum, and the upper part of the vagina and posterior wall of the bladder. The kidneys, suprarenal capsules, and pancreas are covered by the membrane without receiving any special investment from it.

Viscera uncovered by Peritoneum.—The lower end of the rectum, the neck, base, and anterior surface of the bladder, the whole of the front, and the lower part of the posterior wall of the vagina have no peritoneal covering.

Numerous folds are formed by the peritoneum, extending between the various organs. These serve to hold them in position, and at the same time enclose the vessels and nerves proceeding to each part. Some of the folds are called *ligaments*, from their serving to support the organs in position; others, which connect certain parts of the intestine with the abdominal wall, constitute the *mesenteries*; and lastly, those which proceed from the stomach to certain viscera in its neighborhood are called *omenta*.

The **Ligaments**, formed by folds of the peritoneum, include those of the liver, spleen, bladder, and uterus. They will be found described with their respective organs.

The **Omenta** are—the lesser omentum, the great omentum, and the gastro-splenic omentum.

The *lesser omentum (gastro-hepatic)* is the duplicature which extends between the transverse fissure of the liver and the lesser curvature of the stomach. It is extremely thin, and consists of two layers of peritoneum. At the left border its two layers pass on to the end of the œsophagus; but at the right border, where it is free, they are continuous, and form a free rounded margin, which contains between its layers the hepatic artery, the common bile-duct, the portal vein, lymphatics, and the hepatic plexus of nerves,—all these structures being enclosed in loose areolar tissue, called *Glisson's capsule*. Between the layers where they are attached to the stomach lie the gastric artery and the pyloric branch of the hepatic, anastomosing with it.

The *great omentum (gastro-colic)* is the largest peritoneal fold. It consists of four layers of peritoneum, two of which descend from the stomach, one from its anterior, the other from its posterior surface, and, uniting at its lower border, descend in front of the small intestines as low down as the pelvis; they then turn upon themselves, and ascend again as far as the transverse colon, where they separate and enclose that part of the intestine. These separate layers may be easily demonstrated in the young subject, but in the adult they are more or less inseparably blended. The left border of the great omentum is continuous with the gastro-splenic omentum; its right border extends as far only as the duodenum. The great omentum is usually thin, presents a cribriform appearance, and always contains some adipose tissue, which in fat subjects accumulates in considerable quantity. Its use appears to be to protect the intestines from the cold and to facilitate their movement upon each other during their vermicular action. Between its two anterior layers is the anastomosis between the right and left gastro-epiploica arteries.

The *gastro-splenic omentum* is the fold which connects the concave surface of the spleen to the *cul-de-sac* of the stomach, being continuous by its lower border with the great omentum. It contains the splenic vessels and vasa brevia.

The **Mesenteries** are—the mesentery proper, the meso-cæcum, the ascending, transverse, and descending meso-colon, the sigmoid meso-colon, and the meso-rectum.

The *mesentery (μέσων, ἔντερων)*, so called from being connected to the middle of the cylinder of the small intestine, is the broad fold of peritoneum which connects

the convolutions of the jejunum and ileum with the posterior wall of the abdomen. Its *root*, the part connected with the vertebral column, is narrow, about six inches in length, and directed obliquely from the left side of the second lumbar vertebra to the right sacro-iliac symphysis (Fig. 526). Its intestinal border is much longer, and here its two layers separate, so as to enclose the intestine and form its peritoneal coat. Its breadth between its vertebral and intestinal border is about four inches. Its *upper border* is continuous with the under surface of the transverse

FIG. 526.—Diagram devised by Dr. Delépine to show the lines along which the peritoneum leaves the wall of the abdomen to invest the viscera.

meso-colon; its *lower border*, with the peritoneum, covering the cæcum and ascending colon. It serves to retain the small intestines in their position, and contains between its layers the mesenteric vessels and nerves, the lacteal vessels, and mesenteric glands.

The *meso-cæcum* serves to connect the back part of the cæcum with the posterior wall of the abdomen, being continuous with the ascending meso-colon.

The *ascending meso-colon* is the fold which connects the back part of the ascending colon with the posterior wall of the abdomen, and the *descending meso-colon* retains the descending colon in connection with the posterior abdominal

wall; more frequently the peritoneum merely covers the anterior surface and sides of these two portions of the intestine. At the place where the transverse colon turns downward to form the descending colon, a fold of peritoneum is continued upward to the under surface of the Diaphragm opposite the tenth and eleventh ribs. This is the *costo-colic ligament*; it passes below the spleen, and serves to support this organ and prevent it moving.

The *transverse meso-colon* is a broad fold which connects the transverse colon to the posterior wall of the abdomen. It is formed by the two ascending layers of the great omentum, which, after separating to surround the transverse colon, join behind it, and are continued backward to the spine, where they diverge in front of the duodenum. This fold contains between its layers the vessels which supply the transverse colon.

The *sigmoid meso-colon* is the fold of peritoneum which retains the sigmoid flexure in connection with the left iliac fossa.

The *meso-rectum* is the narrow fold which connects the upper part of the rectum with the front of the sacrum. It contains the superior hæmorrhoidal vessels.

The *appendices epiploicæ* are small pouches of the peritoneum filled with fat and situated along the colon and upper part of the rectum. They are chiefly appended to the transverse colon.

THE STOMACH.

The **Stomach** is the principal organ of digestion. It is the most dilated part of the alimentary canal. Its form is irregularly conical, curved upon itself, and presenting a rounded base, turned to the left side. It is placed, in part, immediately behind the anterior wall of the abdomen, and, in part, beneath the liver and Diaphragm and above the transverse colon. It is placed almost vertically in the abdomen, so that the fundus which projects upward and to the left of the œsophageal opening touches the Diaphragm, while the pyloric or lesser extremity is directed downward and to the right, so that the opening by which the stomach communicates with the small intestine is situated slightly to the right of the median line of the body (Fig. 527): the stomach is situated, therefore, for the most part, in the left hypochondriac region, the pyloric extremity occupying, however, the epigastric region. Its size varies considerably in different subjects, and also according to its state of distension. When moderately full its vertical diameter is about twelve inches, its transverse diameter about four. Its weight, according to Clendenning, is about four ounces and a half. It presents for examination two extremities, two orifices, two borders, and two surfaces.

Its *upper extremity* is called the *greater or splenic end*. This is the largest part of the stomach, and extends two or three inches to the left of the point of entrance of the œsophagus. This expanded part is called the *great cul-de-sac*, or *fundus*. It lies behind the lower ribs, in contact with the Diaphragm, and is connected posteriorly to the spleen by the gastro-splenic omentum.

The *lesser or pyloric end* is much smaller than the fundus, and situated on a plane anterior and inferior to it. It lies in contact with the wall of the abdomen and the under surface of the liver. Its position on the surface of the body varies with the degree of distension of the organ. Near the pyloric end there is a double bend in the stomach, attended by an appearance of constriction. The distal bend corresponds to the situation of the pyloric valve, and between the two there is a bulging which is named the *lesser cul-de-sac* or *antrum pylori*.

FIG. 527.—Diagrammatic outline of the stomach.

The *œsophageal* or *cardiac orifice* communicates with the *œsophagus*; it is somewhat funnel-shaped.

The *pyloric orifice* communicates with the duodenum, the aperture being guarded by a kind of valve—the *pylorus*.

The *lesser curvature* extends between the *œsophageal* and *pyloric orifices*, along the right border of the organ, and is connected to the under surface of the liver by the lesser omentum.

The *greater curvature* extends between the same two points, along the left border, and gives attachment to the great omentum. The surfaces of the organ are limited by these two curvatures.

The *anterior surface* is directed upward and forward, and is in relation with the Diaphragm, the under surface of the left lobe of the liver, and with the abdominal parietes.

The *posterior surface* is directed downward and backward, and is in relation with the spleen, the pancreas, the left kidney and suprarenal capsule, and the transverse meso-colon.

The stomach is held in position by the lesser omentum, which extends from the transverse fissure of the liver to its lesser curvature, and by a fold of peritoneum, which passes from the Diaphragm on to the *œsophageal* end of the stomach, the *gastro-phrenic ligament*: this constitutes the most fixed point of the stomach, whilst the *pyloric* end and *greater curvature* are the most movable parts. To its greater curvature is attached the great omentum, by which it is connected to the transverse colon.

Alterations in Position.—There is no organ in the body the position and connections of which present such frequent alterations as the stomach. During *inspiration* it is displaced downward by the descent of the Diaphragm and elevated by the pressure of the abdominal muscles during *expiration*. Its position in relation to the surrounding viscera is also changed according to the empty or distended state of the organ. When *empty* it lies at the back part of the abdomen, some distance from the surface. The left lobe of the liver covers it in front, and the under surface of the heart rests upon it above and in front, being separated from it by the left lobe of the liver, besides the Diaphragm and pericardium. This close relation between the stomach and the heart explains the fact that in *gastralgia* the pain is generally referred to the heart, and is often accompanied by palpitation and intermission of the pulse. When the stomach is *distended* the greater curvature is elevated and carried forward, so that the anterior surface is turned upward and the posterior surface downward, and the stomach brought well against the anterior wall of the abdomen.¹ The Diaphragm at the same time is forced upward, contracting the cavity of the chest; hence the *dyspnoea* complained of, from inspiration being impeded. The heart is also displaced upward; hence the oppression in this region and the palpitation experienced in extreme distension of the stomach. Pressure from without, as from tight lacing, pushes the stomach down toward the pelvis. In disease also the position and connections of the organ may be greatly changed, from the accumulation of fluid in the chest or abdomen or from alteration in size of any of the surrounding viscera.

On looking into the *pyloric* end of the stomach the mucous membrane is found projecting inward in the form of a circular fold, the *pylorus*, leaving a narrow circular aperture, about half an inch in diameter, by which the stomach communicates with the duodenum.

The *pylorus* is formed by a reduplication of the mucous membrane of the stomach, containing numerous muscular fibres, which are aggregated into a thick circular ring, the longitudinal fibres and serous membrane being continued over the fold without assisting in its formation. The aperture is occasionally oval. Sometimes the circular fold is replaced by two crescentic folds, placed one above and the other below the *pyloric orifice*; and more rarely there is only one crescentic fold.

Structure.—The stomach consists of four coats—serous, muscular, areolar, and mucous, together with vessels and nerves.

The *serous coat* is derived from the peritoneum, and covers the entire sur-

¹ This is denied by Dr. Lesshaft of St. Petersburg, who states that "if the stomach is enlarged, no one part can be alone displaced, but all parts are equally moved by the distension" (*Lancet*, March 11, 1882, p. 406).

wall; more frequently the peritoneum merely covers the anterior surface and sides of these two portions of the intestine. At the place where the transverse colon turns downward to form the descending colon, a fold of peritoneum is continued upward to the under surface of the Diaphragm opposite the tenth and eleventh ribs. This is the *costo-colic ligament*; it passes below the spleen, and serves to support this organ and prevent it moving.

The *transverse meso-colon* is a broad fold which connects the transverse colon to the posterior wall of the abdomen. It is formed by the two ascending layers of the great omentum, which, after separating to surround the transverse colon, join behind it, and are continued backward to the spine, where they diverge in front of the duodenum. This fold contains between its layers the vessels which supply the transverse colon.

The *sigmoid meso-colon* is the fold of peritoneum which retains the sigmoid flexure in connection with the left iliac fossa.

The *meso-rectum* is the narrow fold which connects the upper part of the rectum with the front of the sacrum. It contains the superior hæmorrhoidal vessels.

The *appendices epiploicæ* are small pouches of the peritoneum filled with fat and situated along the colon and upper part of the rectum. They are chiefly appended to the transverse colon.

THE STOMACH.

The **Stomach** is the principal organ of digestion. It is the most dilated part of the alimentary canal. Its form is irregularly conical, curved upon itself, and presenting a rounded base, turned to the left side. It is placed, in part, immediately behind the anterior wall of the abdomen, and, in part, beneath the liver and Diaphragm and above the transverse colon. It is placed almost vertically in the abdomen, so that the fundus which projects upward and to the left of the œsophageal opening touches the Diaphragm, while the pyloric or lesser extremity is directed downward and to the right, so that the opening by which the stomach communicates with the small intestine is situated slightly to the right of the median line of the body (Fig. 527): the stomach is situated, therefore, for the most part, in the left hypochondriac region, the pyloric extremity occupying, however, the epigastric region. Its size varies considerably in different subjects, and also according to its state of distension. When moderately full its vertical diameter is about twelve inches, its transverse diameter about four. Its weight, according to Clendenning, is about four ounces and a half. It presents for examination two extremities, two orifices, two borders, and two surfaces.

Its *upper extremity* is called the *greater or splenic end*. This is the largest part of the stomach, and extends two or three inches to the left of the point of entrance of the œsophagus. This expanded part is called the *great cul-de-sac*, or *fundus*. It lies behind the lower ribs, in contact with the Diaphragm, and is connected posteriorly to the spleen by the gastro-splenic omentum.

The *lesser or pyloric end* is much smaller than the fundus, and situated on a plane anterior and inferior to it. It lies in contact with the wall of the abdomen and the under surface of the liver. Its position on the surface of the body varies with the degree of distension of the organ. Near the pyloric end there is a double bend in the stomach, attended by an appearance of constriction. The distal bend corresponds to the situation of the pyloric valve, and between the two there is a bulging which is named the *lesser cul-de-sac* or *antrum pylori*.

FIG. 527.—Diagrammatic outline of the stomach.

brown color over the rest of its surface. In infancy it is of a brighter hue, the vascular redness being more marked. It is thin at the cardiac extremity, but thicker toward the pylorus. During the contracted state of the organ it is thrown into numerous plaits or rugæ, which for the most part have a longitudinal direction, and are most marked toward the lesser end of the stomach and along the greater curvature (Fig. 528). These folds are entirely obliterated when the organ becomes distended.

Structure of the Mucous Membrane.—When examined with a lens the inner surface of the mucous membrane presents a peculiar honeycomb appearance, from being covered with small shallow depressions or alveoli of a polygonal or hexagonal form, which vary from $\frac{1}{100}$ to $\frac{1}{200}$ of an inch in diameter, and are separated by slightly elevated ridges. In the bottom of the alveoli are seen the orifices of minute tubes, the *gastric follicles*, which are situated perpendicularly side by side throughout the entire substance of the mucous membrane.

The gastric follicles are of two kinds, which differ from each other in structure.

FIG. 529.—The muscular coat of the stomach.

and it is believed also in the nature of their secretion. They are named respectively *pyloric* and *peptic glands*. They are both tubular in character, and are formed of a delicate basement membrane, supporting epithelium. The basement membrane consists of flattened transparent endothelial cells, with processes which extend and support the epithelium. The *pyloric glands* (Fig. 530) are most numerous at the pyloric end of the stomach, and from this fact have received their name. They were formerly termed mucous glands, and were supposed to secrete mucus; but, as Klein points out, "the cells are serous, not mucous, and the secretion of the glands cannot therefore be mucus." They consist of two or three short closed tubes opening into a common duct, the external orifice of which is situated at the bottom of an alveolus. The caecal tubes are wavy, and are of about equal length with the duct. The tubes and duct are lined throughout with epithelium, the duct being lined by columnar cells continuous with the epithelium lining the surface of the mucous membrane of the stomach, the tubes with shorter and more cubical cells, which are finely granular. The *peptic glands* (Fig. 531) are found all over the surface of the stomach. Like the pyloric glands, they consist of a duct into which open two or more caecal tubes. The duct, however, in these glands is shorter than in the other

variety, sometimes not amounting to more than one-sixth of the whole length of the gland; it is lined throughout by columnar epithelium. At the point where the terminal tubes open into the duct, and which is termed the neck, the epithelium alters, the cells becoming much shorter and opaque: the lumen also becomes suddenly constricted, and is continued down to the bottom of the tubes as a very fine channel. Here also are found, between the epithelium and the basement membrane, large spheroidal, coarsely granular cells, which were formerly termed *peptic cells*, and which produce an outward bulging of the basement membrane. They are seen throughout the remainder of the tube at intervals, and give it a beaded or varicose appearance. Below the neck the terminal tubes, in addition to these isolated spheroidal cells, are occupied with finely granular, angular cells

FIG. 530.—Pyloric gland.

FIG. 531.—Peptic gastric gland.

(columnar, Klein), leaving only a small channel in the centre. They are continuous with the short columnar cells of the neck, and are termed the *central* or *chief cells*, because they are believed to be principally concerned in the secretion of the gastric juice. The peptic cells, which were formerly supposed to possess this office, are now termed *parietal* or *oxyntic cells*. Between the glands the mucous membrane consists of a connective-tissue framework, with lymphoid tissue. In places this latter tissue, especially in early life, is collected into little masses, which to a certain extent resemble the solitary glands of the intestine, and are by some termed the *lenticular* glands of the stomach. They are not, however, so distinctly circumscribed as the solitary glands. The epithelium lining the mucous membrane of the stomach and its alveoli is of the columnar variety. Beneath the mucous membrane, and between it and the submucous coat, is a thin stratum of involuntary muscular fibre (*muscularis mucosæ*), which in some parts consists only of a single longitudinal layer; in others, of two layers, an inner, circular, and an outer, longitudinal.

Vessels and Nerves.—The arteries supplying the stomach are—the gastric, the pyloric and right gastro-epiploic branches of the hepatic, the left gastro-epiploic and vasa brevia from the splenic. They supply the muscular coat, ramify in the

submucous coat, and are finally distributed to the mucous membrane. The arrangement of the vessels in the mucous membrane is somewhat peculiar. The arteries break up at the base of the gastric tubules into a plexus of fine capillaries which run upward between the tubules, anastomosing with each other, and ending in a plexus of larger capillaries, which surround the mouths of the tubes and also form hexagonal meshes around the alveoli. From these latter the *veins* arise, and pursue a straight course backward between the tubules, to the submucous tissue, and terminate either in the splenic and superior mesenteric veins or directly in the portal vein. The *lymphatics* are numerous; they consist of a superficial and deep set, which pass through the lymphatic glands found along the two curvatures of the organ. The *nerves* are the terminal branches of the right and left pneumogastric, the former being distributed upon the back, and the latter upon the front part of the organ. A great number of branches from the sympathetic also supply the organ.

Surface Form.—The stomach lies for the most part in the left hypochondriac region, but also slightly in the epigastric region, and is partly in contact with the abdominal wall, partly under cover of the lower ribs on the left side, and partly under the left lobe of the liver. Its cardiac orifice is behind the seventh costal cartilage of the left side, about one inch from its junction with the sternum, on a level with the tenth dorsal vertebra. The pyloric orifice is in a vertical line drawn from the right border of the sternum, two and a half or three inches below the level of the sterno-xiphoid articulation. According to Braune, when the stomach is distended the pylorus moves considerably to the right, as much sometimes as three inches. The lesser curvature of the stomach is represented by a curved line with its convexity downward from the cardiac to the pyloric extremities; the greater curvature by a similarly curved line between the same points, but with a curve of much greater extent, so that its lowest point reaches a horizontal line drawn between the tips of the tenth costal cartilages. The fundus of the stomach reaches, on the left side, as high as the level of the sixth chondro-sternal articulation, being a little below and behind the apex of the heart. The portion of the stomach which is in contact with the abdominal walls, and is therefore accessible for opening in the operations of gastrotomy and gastrostomy, is represented by a triangular space, the base of which is formed by a line drawn from the tip of the tenth costal cartilage on the left side to the tip of the ninth costal cartilage on the right, and the sides by two lines drawn from the extremity of the eighth costal cartilage on the left side to the ends of the base line.

Surgical Anatomy.—Operations on the stomach are frequently performed. By "gastrotomy" is meant an incision into the stomach for the removal of a foreign body, the opening being immediately afterward closed—in contradistinction to "gastrostomy," the making of a more or less permanent fistulous opening. *Gastrotomy* is probably best performed by an incision in the linea alba, especially if the foreign body is large, by a cut from the ensiform cartilage to the umbilicus, but may be performed by an incision over the body itself, where this can be felt, or by one of the incisions for gastrostomy, to be mentioned immediately. The peritoneal cavity is opened, and the point at which the stomach is to be incised decided upon. This portion is then brought out of the abdominal wound and sponges carefully packed around. The stomach is now opened by a transverse incision and the foreign body extracted. The wound in the stomach is then closed by Lembert's sutures—i. e. by sutures passed through the peritoneal and muscular coats in such a way that the peritoneal surfaces on each side of the wound are brought into apposition, and in this way the wound is closed. *Gastrostomy* is performed in two stages: The first stage consists in opening the peritoneal cavity and stitching the stomach to the abdominal wall. The second stage consists in opening the stomach after a few days have elapsed and adhesions formed between the peritoneal surfaces of the stomach and abdominal wall. The operation is usually performed by an oblique incision about one finger's breadth below and parallel with the margin of the left costal cartilages, commencing an inch and a half from the median line and being about three inches in length. Some surgeons prefer a straight incision, beginning opposite to the end of the eighth intercostal space, and passing down for three inches over the Rectus abdominis muscle. The skin, fasciæ, and muscles are to be severally divided down to the peritoneum. Howse recommends that the sheath of the Rectus should be opened longitudinally, and the fibres of this muscle separated, and not cut, in the same direction, so as to secure a sphincter-like action around the opening. After the peritoneum has been opened the stomach is recognized by its pink-red color and smooth surface. It is to be pulled up into the wound and sutured to the opening. This may be done in several ways, but in whatever way it is done the following points should be carefully attended to: (1) In taking up the stomach only to pass the needle through the serous and muscular coats, and avoid puncturing the mucous membrane. (2) To take up plenty of the muscular coat. (3) In passing the needle through the parietes of the abdomen to be careful to include the parietal peritoneum. (4) To enclose a circle of the stomach at least an inch in diameter. If the symptoms admit of it, the parts are now to be left quiet for four or five days, and a small puncture is then to be made through the exposed portion of the stomach, and a gum elastic catheter passed through it into the viscus, through which fluid can be injected,

in small quantities at first. In more urgent cases it may be necessary to make the opening much earlier.

Excision of the pylorus has occasionally been performed, but the results of this operation are by no means favorable, and in cases of cancer of the pylorus gastro-enterostomy is generally preferred. The object of this operation is to make a fistulous communication between the stomach, on the cardiac side of the disease, and the small intestine, as high up as is possible.

THE SMALL INTESTINE.

The small intestine is a convoluted tube, about twenty feet in length,¹ which gradually diminishes in size from its commencement to its termination. It is contained in the central and lower parts of the abdominal and pelvic cavities, surrounded above and at the sides by the large intestine; it is in relation, in front, with the great omentum and abdominal parietes, and connected to the spine by a fold of peritoneum, the mesentery. The small intestine is divisible into three portions—the duodenum, the jejunum, and ileum.

The **duodenum** has received its name from being about equal in length to the breadth of twelve fingers (eight or ten inches). It is the shortest, the widest, and the most fixed part of the small intestine; it has no mesentery, and is only partially covered by the peritoneum. Its course presents a remarkable curve, somewhat like a horseshoe in form, the convexity being directed toward the right, and the concavity to the left, embracing the head of the pancreas. Commencing at the pylorus, it passes obliquely upward, backward, and to the right, to the under surface of the liver; it then descends in front of the right kidney, and passes nearly transversely across the front of the spine, terminating in the jejunum on the left side of the second lumbar vertebra. Hence the duodenum has been divided into three portions—ascending, descending, and transverse.

The first, or *ascending portion* (Fig. 532), about two inches in length, is free, movable, and nearly completely invested by the peritoneum, which forms the lesser omentum. It is in relation, above and in front, with the liver and neck of the gall-bladder; behind, with the vessels which run between the layers of the lesser omentum—viz. the hepatic artery and duct, and vena portæ. This portion of the intestine is usually found after death stained with bile, especially on its anterior surface.

The second, or *descending portion*, about three inches in length, is firmly fixed by the peritoneum and pancreas. It passes from the neck of the gall-bladder vertically downward, in front of the right kidney, as far as the third lumbar vertebra. It is covered by peritoneum only on its anterior surface. It is in relation, in front, with the right arch of the colon and the meso-colon; behind, with the front of the right kidney; at its inner side is the head of the pancreas and the ductus communis choledochus. The common bile-duct and the pancreatic duct perforate the inner side of this portion of the intestine obliquely, a little below its middle.

The third, or *transverse portion*, the longest and narrowest part of the duodenum, passes across the front of the spine, ascending from the third to the second lumbar vertebra, and terminating in the jejunum on the left side of the latter bone. In front, though at some distance from it, is the descending layer of the transverse meso-colon, or the divergence of the two layers of that structure, and it is crossed by the superior mesenteric vessels; behind, it rests upon the aorta, the vena cava inferior, and the crura of the Diaphragm; above it is the lower border of the pancreas, the superior mesenteric vessels passing forward between the two.

The point of junction of the duodenum and jejunum is said to correspond to the spot where the gut receives a complete investment of peritoneum. From this point a fairly constant portion, about an inch in length, ascends on the left side of

¹ Treves states that in one hundred cases the average length of the small intestine in the adult male was 22 feet 6 inches, and in the adult female 23 feet 4 inches: but that it varies very much, the extremes in the male being 31 feet 10 inches in one case and 15 feet 6 inches in another, a difference of over 15 feet. He states that he has convinced himself that the length of the bowel is independent, in the adult, of age, height, and weight.

as the lesser omentum, and thus it forms the anterior boundary of the foramen of Winslow. It now covers the front of the stomach, and upon reaching the cardiac extremity it passes to the spleen, which it encloses, forming the gastrosplenic omentum. From the hilum of the spleen it turns backward to reach the abdominal wall, along which it courses to reach the median line of the abdomen.

The *foramen of Winslow* is bounded, *in front*, by the lesser omentum, enclosing

FIG. 525.—Transverse section of peritoneum. (An arrow has been introduced into the foramen of Winslow.)

the vena portæ and the hepatic artery and duct: *behind*, by the inferior vena cava; *above*, by the lobulus Spigelii and lobulus caudatus; *below*, by the hepatic artery curving forward from the celiac axis.

The reflections of the peritoneum over the transverse colon are somewhat differently described by some authors (Luschka, Holden), and there is no doubt, as was long ago pointed out by Haller, that the arrangement in the fœtus is different from that which has been described above. In the fœtus, and even in the young child, the two ascending layers of the great omentum can be traced passing together *over* the transverse colon, instead of embracing it, as described above, and passing back to the spine as a double fold, which can be separated from the transverse colon and transverse meso-colon. Upon reaching the spine the two layers separate: the upper one (the inner of the two ascending layers of the great omentum) passes upward in front of the pancreas and crura of the Diaphragm, forming the posterior boundary of the lesser bag of the peritoneum, in a similar manner to the upper layer of the transverse meso-colon in the former description. The other fold (the outer of the ascending layer of the great omentum) after reaching the spine is turned forward again on itself as far as the transverse colon, which it covers, and is again reflected back to the spine, to pass down in front of the aorta to form the mesentery, in a similar manner to the lower layer of the transverse meso-colon in the former description. Thus the transverse colon is invested by a distinct fold of peritoneum, prolonged forward from the spine to surround it, in a very similar manner to the way in which the small intestines are surrounded.

In the adult, however, as a rule, this arrangement disappears. Probably adhesion of the layers of which the fœtal duplication is composed takes place, and then absorption, and thus the arrangement is brought about which has been described above as most frequently seen in the adult subject. It may be that the fœtal duplicature is "drawn or pushed forward from its place in the progress of visceral development, and thus effaced."¹

Viscera covered by Peritoneum.—The viscera thus shown to be almost entirely

¹ Quain's *Anatomy*, vol. ii. p. 485, 8th ed.

invested by peritoneum are, the liver, stomach, spleen, first portion of the duodenum, the jejunum and ileum, the transverse colon, the cæcum, sigmoid flexure, upper half of the rectum, the uterus, and ovaries.

Viscera Partially covered by Peritoneum.—The viscera only partially invested by peritoneum are—the descending and transverse portions of the duodenum, the ascending and descending colon, the middle portion of the rectum, and the upper part of the vagina and posterior wall of the bladder. The kidneys, suprarenal capsules, and pancreas are covered by the membrane without receiving any special investment from it.

Viscera uncovered by Peritoneum.—The lower end of the rectum, the neck, base, and anterior surface of the bladder, the whole of the front, and the lower part of the posterior wall of the vagina have no peritoneal covering.

Numerous folds are formed by the peritoneum, extending between the various organs. These serve to hold them in position, and at the same time enclose the vessels and nerves proceeding to each part. Some of the folds are called *ligaments*, from their serving to support the organs in position; others, which connect certain parts of the intestine with the abdominal wall, constitute the *mesenteries*; and lastly, those which proceed from the stomach to certain viscera in its neighborhood are called *omenta*.

The **Ligaments**, formed by folds of the peritoneum, include those of the liver, spleen, bladder, and uterus. They will be found described with their respective organs.

The **Omenta** are—the lesser omentum, the great omentum, and the gastro-splenic omentum.

The *lesser omentum (gastro-hepatic)* is the duplicature which extends between the transverse fissure of the liver and the lesser curvature of the stomach. It is extremely thin, and consists of two layers of peritoneum. At the left border its two layers pass on to the end of the œsophagus; but at the right border, where it is free, they are continuous, and form a free rounded margin, which contains between its layers the hepatic artery, the common bile-duct, the portal vein, lymphatics, and the hepatic plexus of nerves,—all these structures being enclosed in loose areolar tissue, called *Glisson's capsule*. Between the layers where they are attached to the stomach lie the gastric artery and the pyloric branch of the hepatic, anastomosing with it.

The *great omentum (gastro-colic)* is the largest peritoneal fold. It consists of four layers of peritoneum, two of which descend from the stomach, one from its anterior, the other from its posterior surface, and, uniting at its lower border, descend in front of the small intestines as low down as the pelvis; they then turn upon themselves, and ascend again as far as the transverse colon, where they separate and enclose that part of the intestine. These separate layers may be easily demonstrated in the young subject, but in the adult they are more or less inseparably blended. The left border of the great omentum is continuous with the gastro-splenic omentum; its right border extends as far only as the duodenum. The great omentum is usually thin, presents a cribriform appearance, and always contains some adipose tissue, which in fat subjects accumulates in considerable quantity. Its use appears to be to protect the intestines from the cold and to facilitate their movement upon each other during their vermicular action. Between its two anterior layers is the anastomosis between the right and left gastro-epiploic arteries.

The *gastro-splenic omentum* is the fold which connects the concave surface of the spleen to the *cul-de-sac* of the stomach, being continuous by its lower border with the great omentum. It contains the splenic vessels and vasa brevia.

The **Mesenteries** are—the mesentery proper, the meso-cæcum, the ascending, transverse, and descending meso-colon, the sigmoid meso-colon, and the meso-rectum.

The *mesentery (μέσων, ἔντερων)*, so called from being connected to the middle of the cylinder of the small intestine, is the broad fold of peritoneum which connects

the convolutions of the jejunum and ileum with the posterior wall of the abdomen. Its *root*, the part connected with the vertebral column, is narrow, about six inches in length, and directed obliquely from the left side of the second lumbar vertebra to the right sacro-iliac symphysis (Fig. 526). Its intestinal border is much longer, and here its two layers separate, so as to enclose the intestine and form its peritoneal coat. Its breadth between its vertebral and intestinal border is about four inches. Its *upper border* is continuous with the under surface of the transverse

FIG. 526.—Diagram devised by Dr. Delépine to show the lines along which the peritoneum leaves the wall of the abdomen to invest the viscera.

meso-colon; its *lower border*, with the peritoneum, covering the caecum and ascending colon. It serves to retain the small intestines in their position, and contains between its layers the mesenteric vessels and nerves, the lacteal vessels, and mesenteric glands.

The *meso-caecum* serves to connect the back part of the caecum with the posterior wall of the abdomen, being continuous with the ascending meso-colon.

The *ascending meso-colon* is the fold which connects the back part of the ascending colon with the posterior wall of the abdomen, and the *descending meso-colon* retains the descending colon in connection with the posterior abdominal

wall; more frequently the peritoneum merely covers the anterior surface and sides of these two portions of the intestine. At the place where the transverse colon turns downward to form the descending colon, a fold of peritoneum is continued upward to the under surface of the Diaphragm opposite the tenth and eleventh ribs. This is the *costo-colic ligament*; it passes below the spleen, and serves to support this organ and prevent it moving.

The *transverse meso-colon* is a broad fold which connects the transverse colon to the posterior wall of the abdomen. It is formed by the two ascending layers of the great omentum, which, after separating to surround the transverse colon, join behind it, and are continued backward to the spine, where they diverge in front of the duodenum. This fold contains between its layers the vessels which supply the transverse colon.

The *sigmoid meso-colon* is the fold of peritoneum which retains the sigmoid flexure in connection with the left iliac fossa.

The *meso-rectum* is the narrow fold which connects the upper part of the rectum with the front of the sacrum. It contains the superior hæmorrhoidal vessels.

The *appendices epiploicæ* are small pouches of the peritoneum filled with fat and situated along the colon and upper part of the rectum. They are chiefly appended to the transverse colon.

THE STOMACH.

The **Stomach** is the principal organ of digestion. It is the most dilated part of the alimentary canal. Its form is irregularly conical, curved upon itself, and presenting a rounded base, turned to the left side. It is placed, in part, immediately behind the anterior wall of the abdomen, and, in part, beneath the liver and Diaphragm and above the transverse colon. It is placed almost vertically in the abdomen, so that the fundus which projects upward and to the left of the œsophageal opening touches the Diaphragm, while the pyloric or lesser extremity is directed downward and to the right, so that the opening by which the stomach communicates with the small intestine is situated slightly to the right of the median line of the body (Fig. 527): the stomach is situated, therefore, for the most part, in the left hypochondriac region, the pyloric extremity occupying, however, the epigastric region. Its size varies considerably in different subjects, and also according to its state of distension. When moderately full its vertical diameter is about twelve inches, its transverse diameter about four. Its weight, according to Clendenning, is about four ounces and a half. It presents for examination two extremities, two orifices, two borders, and two surfaces.

Its *upper extremity* is called the *greater or splenic end*. This is the largest part of the stomach, and extends two or three inches to the left of the point of entrance of the œsophagus. This expanded part is called the great *cul-de-sac*, or *fundus*. It lies behind the lower ribs, in contact with the Diaphragm, and is connected posteriorly to the spleen by the gastro-splenic omentum.

The *lesser or pyloric end* is much smaller than the fundus, and situated on a plane anterior and inferior to it. It lies in contact with the wall of the abdomen and the under surface of the liver. Its position on the surface of the body varies with the degree of distension of the organ. Near the pyloric end there is a double bend in the stomach, attended by an appearance of constriction. The distal bend corresponds to the situation of the pyloric valve, and between the two there is a bulging which is named the *lesser cul-de-sac* or *antrum pylori*.

FIG. 527.—Diagrammatic outline of the stomach.

The *œsophageal* or *cardiac orifice* communicates with the *œsophagus*; it is somewhat funnel-shaped.

The *pyloric orifice* communicates with the duodenum, the aperture being guarded by a kind of valve—the *pylorus*.

The *lesser curvature* extends between the *œsophageal* and *pyloric orifices*, along the right border of the organ, and is connected to the under surface of the liver by the lesser omentum.

The *greater curvature* extends between the same two points, along the left border, and gives attachment to the great omentum. The surfaces of the organ are limited by these two curvatures.

The *anterior surface* is directed upward and forward, and is in relation with the Diaphragm, the under surface of the left lobe of the liver, and with the abdominal parietes.

The *posterior surface* is directed downward and backward, and is in relation with the spleen, the pancreas, the left kidney and suprarenal capsule, and the transverse meso-colon.

The stomach is held in position by the lesser omentum, which extends from the transverse fissure of the liver to its lesser curvature, and by a fold of peritoneum, which passes from the Diaphragm on to the *œsophageal* end of the stomach, the *gastro-phrenic ligament*: this constitutes the most fixed point of the stomach, whilst the pyloric end and greater curvature are the most movable parts. To its greater curvature is attached the great omentum, by which it is connected to the transverse colon.

Alterations in Position.—There is no organ in the body the position and connections of which present such frequent alterations as the stomach. During *inspiration* it is displaced downward by the descent of the Diaphragm and elevated by the pressure of the abdominal muscles during *expiration*. Its position in relation to the surrounding viscera is also changed according to the empty or distended state of the organ. When *empty* it lies at the back part of the abdomen, some distance from the surface. The left lobe of the liver covers it in front, and the under surface of the heart rests upon it above and in front, being separated from it by the left lobe of the liver, besides the Diaphragm and pericardium. This close relation between the stomach and the heart explains the fact that in *gastralgia* the pain is generally referred to the heart, and is often accompanied by palpitation and intermission of the pulse. When the stomach is *distended* the greater curvature is elevated and carried forward, so that the anterior surface is turned upward and the posterior surface downward, and the stomach brought well against the anterior wall of the abdomen.¹ The Diaphragm at the same time is forced upward, contracting the cavity of the chest; hence the *dyspnœa* complained of, from *inspiration* being impeded. The heart is also displaced upward; hence the oppression in this region and the palpitation experienced in extreme distension of the stomach. Pressure from *without*, as from tight lacing, pushes the stomach down toward the pelvis. In disease also the position and connections of the organ may be greatly changed, from the accumulation of fluid in the chest or abdomen or from alteration in size of any of the surrounding viscera.

On looking into the pyloric end of the stomach the mucous membrane is found projecting inward in the form of a circular fold, the *pylorus*, leaving a narrow circular aperture, about half an inch in diameter, by which the stomach communicates with the duodenum.

The *pylorus* is formed by a reduplication of the mucous membrane of the stomach, containing numerous muscular fibres, which are aggregated into a thick circular ring, the longitudinal fibres and serous membrane being continued over the fold without assisting in its formation. The aperture is occasionally oval. Sometimes the circular fold is replaced by two crescentic folds, placed one above and the other below the pyloric orifice; and more rarely there is only one crescentic fold.

Structure.—The stomach consists of four coats—serous, muscular, areolar, and mucous, together with vessels and nerves.

The *serous coat* is derived from the peritoneum, and covers the entire sur-

¹ This is denied by Dr. Lesshaft of St. Petersburg, who states that "if the stomach is enlarged, no one part can be alone displaced, but all parts are equally moved by the distension" (*Lancet*, March 11, 1882, p. 406).

face of the organ, excepting along the greater and lesser curvatures, at the points of attachment of the greater and lesser omenta; here the two layers of peritoneum leave a small triangular space along which the nutrient vessels and nerves pass.

The muscular coat (Fig. 529) is situated immediately beneath the serous covering. It consists of three sets of fibres—longitudinal, circular and oblique.

FIG. 528.—The mucous membrane of the stomach and duodenum with the bile-ducts.

The *longitudinal fibres* are most superficial; they are continuous with the longitudinal fibres of the œsophagus, radiating in a stellate manner from the cardiac orifice. They are most distinct along the curvatures, especially the lesser, but are very thinly distributed over the surfaces. At the pyloric end they are more thickly distributed, and continuous with the longitudinal fibres of the small intestine.

The *circular fibres* form a uniform layer over the whole extent of the stomach beneath the longitudinal fibres. At the pylorus they are most abundant, and are aggregated into a circular ring, which projects into the cavity and forms, with the fold of mucous membrane covering its surface, the *pyloric valve*.

The *oblique fibres* are limited chiefly to the cardiac end of the stomach, where they are disposed as a thick uniform layer covering both surfaces, some passing obliquely from left to right, others from right to left, round the cardiac end. They are continuous with the circular fibres of the œsophagus.

The *areolar coat* consists of a loose, filamentous, areolar tissue, connecting the mucous and muscular layers. It is sometimes called the *submucous coat*. It supports the blood-vessels previous to their distribution to the mucous membrane; hence it is sometimes called the *vascular coat*.

The *mucous membrane* is thick, its surface smooth, soft, and velvety. In the fresh state it is of a pinkish tinge at the pyloric end, and of a red or reddish

brown color over the rest of its surface. In infancy it is of a brighter hue, the vascular redness being more marked. It is thin at the cardiac extremity, but thicker toward the pylorus. During the contracted state of the organ it is thrown into numerous plaits or rugæ, which for the most part have a longitudinal direction, and are most marked toward the lesser end of the stomach and along the greater curvature (Fig. 528). These folds are entirely obliterated when the organ becomes distended.

Structure of the Mucous Membrane.—When examined with a lens the inner surface of the mucous membrane presents a peculiar honeycomb appearance, from being covered with small shallow depressions or alveoli of a polygonal or hexagonal form, which vary from $\frac{1}{100}$ to $\frac{1}{200}$ of an inch in diameter, and are separated by slightly elevated ridges. In the bottom of the alveoli are seen the orifices of minute tubes, the *gastric follicles*, which are situated perpendicularly side by side throughout the entire substance of the mucous membrane.

The gastric follicles are of two kinds, which differ from each other in structure.

FIG. 529.—The muscular coat of the stomach.

and it is believed also in the nature of their secretion. They are named respectively *pyloric* and *peptic glands*. They are both tubular in character, and are formed of a delicate basement membrane, supporting epithelium. The basement membrane consists of flattened transparent endothelial cells, with processes which extend and support the epithelium. The *pyloric glands* (Fig. 530) are most numerous at the pyloric end of the stomach, and from this fact have received their name. They were formerly termed mucous glands, and were supposed to secrete mucus; but, as Klein points out, "the cells are serous, not mucous, and the secretion of the glands cannot therefore be mucus." They consist of two or three short closed tubes opening into a common duct, the external orifice of which is situated at the bottom of an alveolus. The caecal tubes are wavy, and are of about equal length with the duct. The tubes and duct are lined throughout with epithelium, the duct being lined by columnar cells continuous with the epithelium lining the surface of the mucous membrane of the stomach, the tubes with shorter and more cubical cells, which are finely granular. The *peptic glands* (Fig. 531) are found all over the surface of the stomach. Like the pyloric glands, they consist of a duct into which open two or more caecal tubes. The duct, however, in these glands is shorter than in the other

variety, sometimes not amounting to more than one-sixth of the whole length of the gland; it is lined throughout by columnar epithelium. At the point where the terminal tubes open into the duct, and which is termed the neck, the epithelium alters, the cells becoming much shorter and opaque: the lumen also becomes suddenly constricted, and is continued down to the bottom of the tubes as a very fine channel. Here also are found, between the epithelium and the basement membrane, large spheroidal, coarsely granular cells, which were formerly termed *peptic cells*, and which produce an outward bulging of the basement membrane. They are seen throughout the remainder of the tube at intervals, and give it a beaded or varicose appearance. Below the neck the terminal tubes, in addition to these isolated spheroidal cells, are occupied with finely granular, angular cells

FIG. 530.—Pyloric gland.

FIG. 531.—Peptic gastric gland.

(columnar, Klein), leaving only a small channel in the centre. They are continuous with the short columnar cells of the neck, and are termed the *central* or *chief cells*, because they are believed to be principally concerned in the secretion of the gastric juice. The peptic cells, which were formerly supposed to possess this office, are now termed *parietal* or *oxyntic cells*. Between the glands the mucous membrane consists of a connective-tissue framework, with lymphoid tissue. In places this latter tissue, especially in early life, is collected into little masses, which to a certain extent resemble the solitary glands of the intestine, and are by some termed the *lenticular* glands of the stomach. They are not, however, so distinctly circumscribed as the solitary glands. The epithelium lining the mucous membrane of the stomach and its alveoli is of the columnar variety. Beneath the mucous membrane, and between it and the submucous coat, is a thin stratum of involuntary muscular fibre (*muscularis mucosæ*), which in some parts consists only of a single longitudinal layer; in others, of two layers, an inner, circular, and an outer, longitudinal.

Vessels and Nerves.—The arteries supplying the stomach are—the gastric, the pyloric and right gastro-epiploic branches of the hepatic, the left gastro-epiploic and vasa brevia from the splenic. They supply the muscular coat, ramify in the

submucous coat, and are finally distributed to the mucous membrane. The arrangement of the vessels in the mucous membrane is somewhat peculiar. The arteries break up at the base of the gastric tubules into a plexus of fine capillaries which run upward between the tubules, anastomosing with each other, and ending in a plexus of larger capillaries, which surround the mouths of the tubes and also form hexagonal meshes around the alveoli. From these latter the *veins* arise, and pursue a straight course backward between the tubules, to the submucous tissue, and terminate either in the splenic and superior mesenteric veins or directly in the portal vein. The *lymphatics* are numerous; they consist of a superficial and deep set, which pass through the lymphatic glands found along the two curvatures of the organ. The *nerves* are the terminal branches of the right and left pneumogastric, the former being distributed upon the back, and the latter upon the front part of the organ. A great number of branches from the sympathetic also supply the organ.

Surface Form.—The stomach lies for the most part in the left hypochondriac region, but also slightly in the epigastric region, and is partly in contact with the abdominal wall, partly under cover of the lower ribs on the left side, and partly under the left lobe of the liver. Its cardiac orifice is behind the seventh costal cartilage of the left side, about one inch from its junction with the sternum, on a level with the tenth dorsal vertebra. The pyloric orifice is in a vertical line drawn from the right border of the sternum, two and a half or three inches below the level of the sterno-xiphoid articulation. According to Braune, when the stomach is distended the pylorus moves considerably to the right, as much sometimes as three inches. The lesser curvature of the stomach is represented by a curved line with its convexity downward from the cardiac to the pyloric extremities; the greater curvature by a similarly curved line between the same points, but with a curve of much greater extent, so that its lowest point reaches a horizontal line drawn between the tips of the tenth costal cartilages. The fundus of the stomach reaches, on the left side, as high as the level of the sixth chondro-sternal articulation, being a little below and behind the apex of the heart. The portion of the stomach which is in contact with the abdominal walls, and is therefore accessible for opening in the operations of gastrotomy and gastrostomy, is represented by a triangular space, the base of which is formed by a line drawn from the tip of the tenth costal cartilage on the left side to the tip of the ninth costal cartilage on the right, and the sides by two lines drawn from the extremity of the eighth costal cartilage on the left side to the ends of the base line.

Surgical Anatomy.—Operations on the stomach are frequently performed. By "gastrotomy" is meant an incision into the stomach for the removal of a foreign body, the opening being immediately afterward closed—in contradistinction to "gastrostomy," the making of a more or less permanent fistulous opening. *Gastrotomy* is probably best performed by an incision in the linea alba, especially if the foreign body is large, by a cut from the ensiform cartilage to the umbilicus, but may be performed by an incision over the body itself, where this can be felt, or by one of the incisions for gastrostomy, to be mentioned immediately. The peritoneal cavity is opened, and the point at which the stomach is to be incised decided upon. This portion is then brought out of the abdominal wound and sponges carefully packed around. The stomach is now opened by a transverse incision and the foreign body extracted. The wound in the stomach is then closed by Lembert's sutures—i. e. by sutures passed through the peritoneal and muscular coats in such a way that the peritoneal surfaces on each side of the wound are brought into apposition, and in this way the wound is closed. *Gastrostomy* is performed in two stages: The first stage consists in opening the peritoneal cavity and stitching the stomach to the abdominal wall. The second stage consists in opening the stomach after a few days have elapsed and adhesions formed between the peritoneal surfaces of the stomach and abdominal wall. The operation is usually performed by an oblique incision about one finger's breadth below and parallel with the margin of the left costal cartilages, commencing an inch and a half from the median line and being about three inches in length. Some surgeons prefer a straight incision, beginning opposite to the end of the eighth intercostal space, and passing down for three inches over the Rectus abdominis muscle. The skin, fasciæ, and muscles are to be severally divided down to the peritoneum. Howse recommends that the sheath of the Rectus should be opened longitudinally, and the fibres of this muscle separated, and not cut, in the same direction, so as to secure a sphincter-like action around the opening. After the peritoneum has been opened the stomach is recognized by its pink-red color and smooth surface. It is to be pulled up into the wound and sutured to the opening. This may be done in several ways, but in whatever way it is done the following points should be carefully attended to: (1) In taking up the stomach only to pass the needle through the serous and muscular coats, and avoid puncturing the mucous membrane. (2) To take up plenty of the muscular coat. (3) In passing the needle through the parietes of the abdomen to be careful to include the parietal peritoneum. (4) To enclose a circle of the stomach at least an inch in diameter. If the symptoms admit of it, the parts are now to be left quiet for four or five days, and a small puncture is then to be made through the exposed portion of the stomach, and a gum elastic catheter passed through it into the viscus, through which fluid can be injected.

in small quantities at first. In more urgent cases it may be necessary to make the opening much earlier.

Excision of the pylorus has occasionally been performed, but the results of this operation are by no means favorable, and in cases of cancer of the pylorus gastro-enterostomy is generally preferred. The object of this operation is to make a fistulous communication between the stomach, on the cardiac side of the disease, and the small intestine, as high up as is possible.

THE SMALL INTESTINE.

The small intestine is a convoluted tube, about twenty feet in length,¹ which gradually diminishes in size from its commencement to its termination. It is contained in the central and lower parts of the abdominal and pelvic cavities, surrounded above and at the sides by the large intestine; it is in relation, in front, with the great omentum and abdominal parietes, and connected to the spine by a fold of peritoneum, the mesentery. The small intestine is divisible into three portions—the duodenum, the jejunum, and ileum.

The **duodenum** has received its name from being about equal in length to the breadth of twelve fingers (eight or ten inches). It is the shortest, the widest, and the most fixed part of the small intestine; it has no mesentery, and is only partially covered by the peritoneum. Its course presents a remarkable curve, somewhat like a horseshoe in form, the convexity being directed toward the right, and the concavity to the left, embracing the head of the pancreas. Commencing at the pylorus, it passes obliquely upward, backward, and to the right, to the under surface of the liver; it then descends in front of the right kidney, and passes nearly transversely across the front of the spine, terminating in the jejunum on the left side of the second lumbar vertebra. Hence the duodenum has been divided into three portions—ascending, descending, and transverse.

The first, or *ascending portion* (Fig. 532), about two inches in length, is free, movable, and nearly completely invested by the peritoneum, which forms the lesser omentum. It is in relation, above and in front, with the liver and neck of the gall-bladder; behind, with the vessels which run between the layers of the lesser omentum—viz. the hepatic artery and duct, and vena portæ. This portion of the intestine is usually found after death stained with bile, especially on its anterior surface.

The second, or *descending portion*, about three inches in length, is firmly fixed by the peritoneum and pancreas. It passes from the neck of the gall-bladder vertically downward, in front of the right kidney, as far as the third lumbar vertebra. It is covered by peritoneum only on its anterior surface. It is in relation, in front, with the right arch of the colon and the meso-colon; behind, with the front of the right kidney; at its inner side is the head of the pancreas and the ductus communis choledochus. The common bile-duct and the pancreatic duct perforate the inner side of this portion of the intestine obliquely, a little below its middle.

The third, or *transverse portion*, the longest and narrowest part of the duodenum, passes across the front of the spine, ascending from the third to the second lumbar vertebra, and terminating in the jejunum on the left side of the latter bone. In front, though at some distance from it, is the descending layer of the transverse meso-colon, or the divergence of the two layers of that structure, and it is crossed by the superior mesenteric vessels; behind, it rests upon the aorta, the vena cava inferior, and the crura of the Diaphragm; above it is the lower border of the pancreas, the superior mesenteric vessels passing forward between the two.

The point of junction of the duodenum and jejunum is said to correspond to the spot where the gut receives a complete investment of peritoneum. From this point a fairly constant portion, about an inch in length, ascends on the left side of

¹ Treves states that in one hundred cases the average length of the small intestine in the adult male was 22 feet 6 inches, and in the adult female 23 feet 4 inches; but that it varies very much, the extremes in the male being 31 feet 10 inches in one case and 15 feet 6 inches in another, a difference of over 15 feet. He states that he has convinced himself that the length of the bowel is independent, in the adult, of age, height, and weight.

the vertebral column, and is by some regarded as a fourth part of the duodenum. This portion is fixed in this position by a band which extends upward from it, obliquely across the aorta to the connective tissue around the celiac axis and the left crus of the Diaphragm, and is termed the *musculus suspensorius duodeni*, from possessing, according to Treitz, plain muscular fibres, mixed with the fibrous tissue of which it is principally made up.

Vessels and Nerves.—The *arteries* supplying the duodenum are the pyloric and pancreatico-duodenal branches of the hepatic and the inferior pancreatico-duodenal

FIG. 532.—Relations of the duodenum. (A portion of the stomach has been cut away.)

branch of the superior mesenteric. The *veins* terminate in the splenic and superior mesenteric. The *nerves* are derived from the solar plexus.

The *jejunum* (*jejunus*, empty), so called from being usually found empty after death, includes the upper two-fifths of the small intestine below the duodenum. It commences at the duodenum on the left side of the second lumbar vertebra, and terminates in the ileum, its convolutions being chiefly confined to the umbilical and left iliac regions. The jejunum is wider, its coats thicker, more vascular, and of a deeper color than those of the ileum; but there is no characteristic mark to distinguish the termination of the one and the commencement of the other.

The **ileum** (*εἰλεῖν*, to twist), so called from its numerous coils or convolutions, includes the remaining three-fifths of the small intestine. It occupies chiefly the umbilical, hypogastric, right iliac, and occasionally the pelvic regions, and terminates in the right iliac fossa by opening into the inner side of the commencement of the large intestine. The ileum is narrower, its coats thinner and less vascular than those of the jejunum, a given length of it weighing less than the same length of the jejunum.

Meckel's diverticulum.—Occasionally there may be found connected with the lower part of the ileum, from one to three feet from its termination, a blind diverticulum or tube varying in length. It is attached to and communicates with the free margin of the bowel by one extremity, and by the other is unattached, or may be connected with the abdominal wall or some other portion of the intestine by a fibrous band. This is Meckel's diverticulum, and represents the remains of the vitelline duct, or duct of communication between the umbilical vesicle and the alimentary canal (see page 109).

Structure.—The wall of the small intestine is composed of four coats—serous, muscular, areolar, and mucous.

The *serous coat* is derived from the peritoneum. The first or ascending portion of the duodenum is almost completely surrounded by that membrane; the second or descending portion is covered by it only in front; and the third or transverse portion lies behind the descending layer of the transverse meso-colon, which passes over it without being closely incorporated with the other coats of this part of the intestine. The remaining portion of the small intestine is surrounded by the peritoneum, excepting along its attached or mesenteric border; here a space is left for the vessels and nerves to pass to the gut.

The *muscular coat* consists of two layers of fibres, an external or longitudinal and an internal or circular layer. The *longitudinal fibres* are thinly scattered over the surface of the intestine, and are more distinct along its free border. The *circular fibres* form a thick, uniform layer; they surround the cylinder of the intestine in the greater part of its circumference, but do not form complete rings. The muscular coat is thicker at the upper than at the lower part of the small intestine.

The *areolar or submucous coat* connects together the mucous and muscular layers. It consists of loose, filamentous areolar tissue, which forms a nidus for the subdivision of the nutrient vessels previous to their distribution to the mucous surface.

The *mucous membrane* is thick and highly vascular at the upper part of the small intestine, but somewhat paler and thinner below. It consists of the following structures: next the areolar or submucous coat is a layer of unstriped muscular fibres, the *muscularis mucosæ*; internal to this is a quantity of retiform tissue, enclosing in its meshes lymph-corpuscles, and in which the blood-vessels and nerves ramify. Lastly, a basement membrane, supporting a single layer of epithelial cells, which throughout the intestines are columnar in character. They are granular in appearance and possess a clear oval nucleus. At their superficial or unattached end they present a distinct layer of highly refracting material, marked by vertical striæ, which were formerly believed to be minute channels, by which the chyle was taken up into the interior of the cell, and by them transferred to the lacteal vessels of the mucous membrane.

The mucous membrane presents for examination the following structures, contained within it or belonging to it:

Valvulæ conniventes.

Villi.

Simple follicles.

Glands	{ Duodenal glands.
	{ Solitary glands.
	{ Agminate or Peyer's glands.

The **valvulæ conniventes** (valves of Kerkring) are reduplications or foldings of the mucous membrane and submucous tissue. Unlike the folds in the stomach, they are permanent, and are not obliterated when the intestine is distended. They extend transversely across the cylinder of the intestine for about one-half

or two-thirds of its circumference. The larger folds are about two inches in length and one-third of an inch in depth at their broadest part, but the greater number are of smaller size. The larger and smaller folds alternate with each other. They are not found at the commencement of the duodenum, but begin to appear about one or two inches beyond the pylorus. In the lower part of the descending portion, below the point where the common choledic and pancreatic ducts enter the intestine, they are very large and closely approximated. In the transverse portion of the duodenum and upper half of the jejunum they are large and numerous, and from this point, down to the middle of the ileum, they

FIG. 533.—Diagrammatic section of a villus. (Watney.) *cp*, Epithelium only partially shaded in. *t*, Central chyle-vessel; the cells forming the vessel have been less shaded to distinguish them from the cells of the parenchyma of the villus. *m*, Muscle-fibres running up by the side of the chyle-vessel. It will be noticed that each muscle-fibre is surrounded by the reticulum, and by this reticulum the muscles are attached to the cells forming the membrana propria, as at *e*, or to the reticulum of the villus. *lc*, Lymph-corpuscles, marked by a spherical nucleus and a clear zone of protoplasm. *r*, Upper limit of the chyle-vessel. *e, e, e*, Cells forming the membrana propria. It will be seen that there is hardly any difference between the cells of the parenchyma, the endothelium of the upper part of the chyle-vessel, and the cells of the membrana propria. *v*, Blood-vessel. *z*, Dark line at the base of the epithelium formed by the reticulum. It will be seen that the reticulum penetrates between all the other elements of the villus. The reticulum contains thickenings or "nodal points." The diagram shows that the cells of the upper part of the villus are larger and contain a larger zone of protoplasm than those of the lower part. The cells of the upper part of the chyle-vessel differ somewhat from those of the lower part, in that they more nearly resemble the cells of the parenchyma.

diminish considerably in size. In the lower part of the ileum they almost entirely disappear; hence the comparative thinness of this portion of the intestine as compared with the duodenum and jejunum. The valvulae conniventes retard the passage of the food along the intestines and afford a more extensive surface for absorption.

The villi are minute, highly vascular processes projecting from the mucous membrane of the small intestine throughout its whole extent, and giving to its surface a velvety appearance. In shape some are triangular and laminated, others conical or cylindrical, with clubbed or filiform extremities. They are largest and most numerous in the duodenum and jejunum, and become fewer and smaller in the ileum. Krause estimates their number in the upper part of the small intestine at from fifty to ninety in a square line, and in the lower part from forty to seventy, the total number for the whole length of the intestine being about four millions.

Structure of the Villi (Fig. 533).—The structure of the villi has been studied recently by many eminent anatomists. We shall here follow the description of Dr. Watney,¹ whose researches have a most important bearing on the physiology

FIG. 534.—Villi of small intestine. (Cadiat.)

of that which is the peculiar function of this part of the intestine, the absorption of fat.

The essential parts of a villus are—the lacteal vessel, the blood-vessels, the epithelium, the basement membrane and muscular tissue of the mucosa, these structures being supported and held together by retiform lymphoid tissue.

These structures are arranged in the following manner: Situated in the centre of the villus is the lacteal, terminating near the summit in a blind extremity; running along this vessel are unstriated muscular fibres; surrounding it is a plexus of capillary vessels, the whole being enclosed by a basement membrane, supporting columnar epithelium. Those structures which are contained within the basement membrane—namely, the lacteal, the muscular tissue, and the blood-vessels—are surrounded and enclosed by a delicate reticulum which forms the matrix of the villus, and in the meshes of which are found large flattened cells, with an oval nucleus, and, in smaller numbers, lymph-corpuscles. These latter are to be distinguished from the larger cells of the villus by their behavior with reagents, by their size, and by the shape of their nucleus, which is spherical. Transitional forms, however, of all kinds are met with between the lymph-corpuscle and the proper cells of the villus.

The *lacteals* are in some cases double, and in some animals multiple. Situated in the axis of the villi, they commence by dilated cæcal extremities near to, but not quite at, the summit of the villus. The walls are composed of a single layer of endothelial cells, the interstitial substance between the cells being continuous with the reticulum of the matrix.

The *muscular fibres* are derived from the muscularis mucosæ, and are arranged in bundles around the lacteal vessel, extending from the base to the summit of the villus, and giving off laterally, individual muscle-cells, which are enclosed by the reticulum, and by it are attached to the basement membrane.

The *blood-vessels* form a plexus between the lacteal and the basement mem-

¹ *Phil. Trans.*, vol. clxvi. pt. ii.

brane, and are enclosed in the reticular tissue; in the interstices of the capillary plexus, which they form, are contained the cells of the villus.

These structures are surrounded by the basement membrane, which is made up of a stratum of endothelial cells, and upon which is placed a layer of columnar epithelium. The reticulum of the matrix is continuous through the basement membrane (that is, through the interstitial substance between the individual endothelial cells) with the interstitial cement substance of the columnar cells on the surface of the villus. Thus we are enabled to trace a direct continuity between the interior of the lacteal and the surface of the villus by means of the reticular tissue, and it is along this path that, according to Dr. Wainey, the chyle passes in the process of absorption by the villi. That is to say, it passes through the interstitial substance between the epithelium cells, through the interstitial substance of the basement membrane, the reticulum of the matrix, and the interstitial substance between the endothelial plates of the lacteal, all which structures have been shown to be continuous with one another, and, being probably semifluid, do not offer any obstacle to the passage of the molecular basis of the chyle.

The **simple follicles**, or *crypts of Lieberkühn* (Figs. 535, 536), are found in considerable numbers over every part of the mucous membrane of the small intestine.

FIG. 535.—Transverse section of crypts of Lieberkühn. (Klein and Noble Smith.)

They consist of minute tubular depressions of the mucous membrane, arranged perpendicularly to the surface, upon which they open by small circular apertures. They may be seen with the aid of a lens, their orifices appearing as minute dots scattered between the villi. Their walls are thin, consisting of a layer of basement membrane (which is, in fact, an endothelial membrane) lined by columnar epithelium, and covered on their exterior by capillary vessels.

The **duodenal** or **Brunner's glands** are limited to the duodenum and commencement of the jejunum. They are small, flattened, granular bodies imbedded in the submucous areolar tissue, and open upon the surface of the mucous membrane by minute excretory ducts.

They are most numerous and largest near the pylorus. They may be compared to the elementary lobules of a salivary gland spread out over a broad surface.

FIG. 536.—Longitudinal section of crypts of Lieberkühn. Goblet-cells seen among the columnar epithelial cells. (Klein and Noble Smith.)

instead of being collected in a mass. They consist of a number of tubular alveoli lined by epithelium, and opening by a single duct on the inner surface of the intestine.

The **solitary glands** (*glandulæ solitariae*) are found scattered throughout the mucous membrane of the small intestine, but are most numerous in the lower part of the ileum. They are small, round, whitish bodies, from half a line to a line in diameter. Their free surface is covered with villi, and each gland is surrounded by the openings of the follicles of Lieberkühn. They are now recognized as lymph-follicles, and consist of a dense interlacing retiform tissue, closely packed with lymph-corpuscles and permeated with an abundant capillary network (Fig. 537). The interspaces of the retiform tissue are continuous with larger lymph-spaces at the base of the gland through which they communicate with the lacteal system. They are situated partly in the submucous tissue, partly in the mucous

membrane, where they form slight projections of its epithelial layer after having penetrated the muscularis mucosæ. The villi which are situated on them are generally absent from the very summit (or "cupola," as Frey calls it) of the gland.

Peyer's glands (Figs. 536-540) may be regarded as aggregations of solitary glands, forming circular or oval patches from twenty to thirty in number, and varying in length from half an inch to four inches. They are largest and most numerous in the ileum. In the lower part of the jejunum they are small, of a circular form, and few in number. They are occasionally seen in the duodenum. They are placed lengthwise in the intestine, covering the portion of the tube most distant from the attachment of the mesentery. Each patch is formed of a group of the above-described solitary glands covered with mucous membrane, and in almost every respect are similar in structure to them. They do not, however, as a rule, possess villi on their free surface. Each patch is surrounded by a circle of the crypts of Lieberkühn. They are best marked in the young subject, becoming indistinct in middle age, and sometimes altogether disappearing in

FIG. 537.—Transverse section through the equatorial plane of three of Peyer's follicles from the rabbit.

FIG. 538.—Patch of Peyer's glands. From the lower part of the ileum.

FIG. 539.—A portion of the above magnified.

advanced life. They are largely supplied with blood-vessels, which form an abundant plexus around each follicle, from which fine branches are given off which permeate the lymphoid tissue in the interior of the follicle.

Vessels and Nerves.—The jejunum and ileum are supplied by the superior mesenteric artery, the branches of which, having reached the attached border of the bowel, run between the serous and muscular coats, with frequent anastomoses to the free border, where they also anastomose with other branches running round the opposite surface of the gut. From these vessels numerous branches are given off which pierce the muscular coat, supplying it and forming an intricate plexus in the submucous tissue. From this plexus minute vessels

pass to the glands and villi of the mucous membrane. The veins have a similar course and arrangement to the arteries. The lymphatics of the small

intestine (lacteals) are arranged in two sets, those of the villi and those of the

FIG. 541.—Meissner's plexus. (Klein and Noble Smith.)

muscular coat. The lymphatics of the villi commence in these structures in the manner described above, and form an intricate plexus in the mucous and

submucous tissue, being joined by the lymphatics from the lymph-spaces at the bases of the solitary glands (Fig. 540), and from this pass to larger vessels at the mesenteric border of the gut. The lymphatics of the muscular coats are situated to a great extent between the two layers of muscular fibres, where they form a close plexus, and throughout their course communicate freely with the lymphatics from the mucous membrane, and empty themselves in the same manner into the commencement of the lacteal vessels at the attached border of the gut.

The *nerves of the small intestine* are derived from the plexuses of sympathetic nerves around the superior mesenteric artery. From this source they run to a plexus of nerves and ganglia situated between the circular and longitudinal muscular fibres (Auerbach's plexus) from which the nervous branches are distributed to the muscular coats of the intestine. From this plexus a secondary plexus is derived (Meissner's plexus), which is formed by branches which have perforated the circular muscular fibres (Fig. 541). This plexus lies between the muscular and mucous coats of the intestine. It is also gangliated, and from it the ultimate fibres pass to the muscularis mucosæ and to the mucous membrane.

THE LARGE INTESTINE.

The large intestine extends from the termination of the ileum to the anus. It is about five feet in length, being one-fifth of the whole extent of the intestinal canal. It is largest at its commencement at the cæcum, and gradually diminishes as far as the rectum, where there is a dilatation of considerable size just above the anus. It differs from the small intestine in its greater size, its more fixed position and its sacculated form. The large intestine in its course describes an arch, which surrounds the convolutions of the small intestine. It commences in the right inguinal region, in a dilated part, the *cæcum*. It ascends through the right lumbar and hypochondriac regions to the under surface of the liver; passes transversely across the abdomen, on the confines of the epigastric and umbilical regions, to the left hypochondriac region; descends through the left lumbar region to the left iliac fossa, where it becomes convoluted and forms the sigmoid flexure; finally it enters the pelvis, and descends along its posterior wall to the anus. The large intestine is divided into the cæcum, colon, and rectum.

The *cæcum* (*cæcus*, blind) (Fig. 542) is the large blind pouch, or *cul-de-sac*, in which the large intestine commences. It is the most dilated part of the tube, measuring about two and a half inches both in its vertical and transverse diameters. Its position varies somewhat; usually it is found lying upon the Psoas muscle, and so placed that its apex or lowest point is just projecting beyond the inner border of that muscle, corresponding to a point a little to the inner side of the middle of Poupart's ligament. Sometimes, however, it is situated external to this, in the right iliac fossa, in relation with the Iliacus muscle; and at other times it lies internal to both Psoas and Iliacus, either resting on the pelvic brim or altogether contained within the pelvis. It is entirely enveloped on all sides by peritoneum, which after enclosing it is reflected on to the posterior wall of the abdomen, being continuous with the ascending meso-colon when this fold exists. The cæcum, therefore, lies quite free in the abdominal cavity, and enjoys a considerable amount of movement. On its inner side it is joined by the ileum, while attached to its lower and back part is the appendix vermiformis.

The *appendix vermiformis* is a long, narrow, worm-shaped tube, the rudiment of the lengthened cæcum found in nearly all the mammalia. The appendix varies from three to six inches in length, its average diameter being about equal to that of a goosequill. It is usually directed upward and inward behind the cæcum, coiled upon itself, and terminates in a blunt point, being retained in its position by a fold of peritoneum, which sometimes forms a mesentery for it.

Its canal is small, and communicates with the cæcum by an orifice which is placed below and behind that of the ileum. It is sometimes guarded with an incomplete valve formed of a fold of mucous membrane. Its coats are thick, and its mucous lining furnished with a large number of solitary glands.

FIG. 542.—The cæcum and colon laid open to show the ileo-cæcal valve.

In the neighborhood of the cæcum, and especially in the vicinity of the ileo-cæcal valve, are certain pouches of peritoneum or fossæ which are of surgical importance. Three of these fossæ have been described. The *ileo-colic fossa* (superior ileo-cæcal) is situated at the junction of the ileum and colon, in the angle between the ascending colon, which forms the outer boundary of the pouch, and the ileum which forms the lower boundary. Often a fold of peritoneum, arching over a branch of the ileo-colic artery, roofs in this angle, and thus forms a pouch the floor of which is formed by the mesentery. The *ileo-cæcal fossa* (inferior ileo-cæcal) is situated behind the angle of junction of the ileum and cæcum. It is formed by a fold of peritoneum (ileo-cæcal fold), which extends from the border of the ileum,

and, passing over the ileo-cæcal junction, joins the mesentery of the appendix. Between this fold and the appendix is the fossa, which is bounded to the right by the ascending meso-colon and to the left by the mesentery. It may extend a considerable distance upward, behind and parallel with the colon. The *subcæcal fossa* (retro-cæcal) is situated immediately beneath the cæcum, which has to be raised to bring it into view. It lies close to the ileo-cæcal fossa, from which it is separated by the meso-cæcum and ascending meso-colon. It is not so constant as either the ileo-cæcal or ileo-colic fossæ.

Hernia of the vermiform appendix into one of these pouches frequently takes place, when it is often concealed and might escape the search of the surgeon were he not familiar with their existence. Moreover, a herniated appendix into one of these pouches is very liable to become strangulated. The presence of these pouches also explains the course which pus has been known to take in cases of perforation of the appendix, where it travels upward behind the ascending colon as far as the Diaphragm.¹

Ileo-cæcal valve.—The lower end of the ileum terminates at the inner and back part of the large intestine, opposite the junction of the cæcum with the colon. At this point the mucous membrane forms two valvular folds, which project into the large intestine and are separated from each other by a narrow, elongated aperture. These folds form the ileo-cæcal valve (*valvula Bauhini*). Each fold is semilunar in form. The upper one, nearly horizontal in direction, is attached by its convex border to the point of junction of the ileum with the colon; the lower segment, to the point of junction of the ileum with the cæcum. Their free concave margins project into the intestine, separated from one another by a narrow slit-like aperture directed transversely. At each end of this aperture the two segments of the valve coalesce, and are continued as a narrow membranous ridge round the canal of the intestine for a short distance, forming the *fræna*, or *retinacula*, of the valve. The left or anterior end of this aperture is rounded; the right or posterior end is narrow and pointed.

Each segment of the valve is formed by a reduplication of the mucous

¹ On the anatomy of these fossæ see a paper by Dr. Rolleston and Mr. Lockwood (*Journal of Anatomy and Physiology*, vol. xxvi. p. 130).

membrane and of the circular muscular fibres of the intestine, the longitudinal fibres and peritoneum being continued uninterruptedly across from one intestine to the other. When these are divided or removed the ileum may be drawn outward, and all traces of the valve will be lost, the ileum appearing to open into the large intestine by a funnel-shaped orifice of large size.

The surface of each segment of the valve directed toward the ileum is covered with villi, and presents the characteristic structure of the mucous membrane of the small intestine, whilst that turned toward the large intestine is destitute of villi, and marked with the orifices of the numerous tubular glands peculiar to the membrane in the large intestine. These differences in structure continue as far as the free margin of the valve.

When the cæcum is distended the margins of the opening are approximated, so as to prevent any reflux into the ileum.

The colon is divided into four parts—the ascending, transverse, descending, and the sigmoid flexure.

The **ascending colon** is smaller than the cæcum. It passes upward from its commencement at the cæcum, opposite the ileo-cæcal valve, to the under surface of the liver on the right of the gall-bladder, where it bends abruptly inward to the left, forming the *hepatic flexure*. It is retained in contact with the posterior wall of the abdomen by the peritoneum, which covers its anterior surface and sides, its posterior surface being connected by loose areolar tissue with the Quadratus lumborum, right kidney, and descending portion of the duodenum (Figs. 543, 544): sometimes the peritoneum almost completely invests it and forms a distinct but narrow meso-colon.¹ It is in relation, in front, with the convolutions of the ileum and the abdominal parietes; behind, it lies on the Quadratus lumborum muscle and right kidney and descending portion of the duodenum.

The **transverse colon**, the longest part of the large intestine, passes transversely from right to left across the abdomen, opposite the confines of the epigastric and umbilical zones, into the left hypochondriac region, where it curves downward beneath the lower end of the spleen, forming the *splenic flexure*. In its course it describes an arch, the concavity of which is directed backward toward the vertebral column; hence the name *transverse arch of the colon*. This is the most movable part of the colon, being almost completely invested by peritoneum, and connected to the spine behind by a large and wide duplicature of that membrane, the *transverse meso-colon*. It is in relation, by its upper surface, with the liver and gall-bladder, the great curvature of the stomach, and the lower end of the spleen; by its under surface, with the small intestines; by its anterior surface, with the anterior layers of the great omentum and the abdominal parietes; by its posterior surface, with the transverse meso-colon and third portion of the duodenum.

The **descending colon** passes almost vertically downward through the left hypochondriac and lumbar regions to the upper part of the left iliac fossa, where it terminates in the sigmoid flexure. It is retained in position by the peritoneum, which covers its anterior surface and sides, its posterior surface being connected by areolar tissue with the left crus of the Diaphragm, the left kidney, and the Quadratus lumborum (Figs. 542, 543). It is smaller in calibre and more deeply placed than the ascending colon, and is more frequently covered with peritoneum on its posterior surface than the ascending colon (Treves).

The **sigmoid flexure** is the narrowest part of the colon: it is situated in the left iliac fossa, commencing from the termination of the descending colon at the

¹ Mr. Treves states that, after a careful examination of one hundred subjects, he found that in fifty-two there was neither an ascending nor a descending meso-colon. In twenty-two there was a descending meso-colon, but no trace of a corresponding fold on the other side. In fourteen subjects there was a meso-colon to both the ascending and the descending segments of the bowel, while in the remaining twelve there was an ascending meso-colon, but no corresponding fold on the left side. It follows, therefore, that in performing lumbar colotomy a meso-colon may be expected upon the left side in 36 per cent. of all cases, and on the right in 26 per cent. (*The Anatomy of the Intestinal Canal and Peritoneum in Man*, 1885, p. 55.)

margin of the crest of the ilium, and ending in the rectum opposite the left sacro-iliac symphysis. It curves in the first place inward, across the Psoas muscle; it

FIG. 543.—Diagram of the relations of the large intestine and kidney, from behind.

then descends vertically along the left wall of the pelvis, and finally again passes inward to the left sacro-iliac joint, where it becomes the rectum. It is retained in its place by a loose fold of peritoneum, the *sigmoid meso-colon*. It is in relation in front, with the small intestines and abdominal parietes.¹

¹ Treves describes the sigmoid flexure somewhat differently. He includes in his description of

The **rectum** is the terminal part of the large intestine, and extends from the

FIG. 344.—The relations of the viscera and large vessels of the abdomen. (Seen from behind, the last dorsal vertebra being well raised.)

sigmoid flexure to the anus: it varies in length from six to eight inches, and has received its name from being less flexuous than any other part of the intestinal this portion of the bowel the upper part of the rectum, and makes it terminate opposite the third portion of the sacrum. Instead of forming a sigmoid curve, he describes it as a large loop or bend, more like the Greek letter Ω (omega).

canal. It commences opposite the left sacro-iliac symphysis, passes obliquely downward from left to right to the middle of the sacrum, forming a gentle curve to the right side; it then descends in front of the lower part of the sacrum and coccyx, presenting a curve with its concavity forward, and near the extremity of the latter bone inclines backward to terminate at the anus. The rectum is, therefore, not straight, the upper part being directed obliquely from the left side to the median line, the middle portion being curved in the direction of the hollow of the sacrum and coccyx, and the lower portion presenting a short curve in the opposite direction. The rectum is cylindrical, not sacculated like the rest of the large intestine; it is narrower at its upper part than the sigmoid flexure, gradually increases in size as it descends, and immediately above the anus presents a considerable dilatation, capable of acquiring an enormous size. The rectum is divided into three portions—upper, middle, and lower.

The *upper portion*, which includes about half the length of the tube, extends obliquely from the left sacro-iliac symphysis to the middle of the third piece of the sacrum. It is almost completely surrounded by peritoneum, and connected to the sacrum behind by a duplicature of that membrane, the *meso-rectum*. It is in relation, behind, with the Pyriformis muscle, the sacral plexus of nerves, and the branches of the internal iliac artery of the left side, which separate it from the sacrum and sacro-iliac symphysis; in front, it is separated, in the male, from the posterior surface of the bladder; in the female, from the posterior surface of the uterus and its appendages by some convolutions of the small intestine.

The *middle portion of the rectum* is about three inches in length, and extends as far as the tip of the coccyx. It is closely connected to the concavity of the sacrum, and covered by peritoneum only on the upper part of its anterior surface. It is in relation, in front, in the male, with the triangular portion of the base of the bladder, the vesiculæ seminales, and vasa deferentia; more anteriorly, with the under surface of the prostate. In the female, with the posterior wall of the vagina, to which it is adherent.

The *lower portion* is about an inch or an inch and a half in length: it curves backward at the fore part of the prostate gland and terminates at the anus. This portion of the intestine receives no peritoneal covering. It is invested by the Internal sphincter, supported by the Levatores ani muscles, and surrounded at its termination by the External sphincter. In the male it is separated from the membranous portion and bulb of the urethra by a triangular space, and in the female a similar space intervenes between it and the vagina. The base of this space forms the perinæum. The rectum in the female is more capacious and less curved than in the male.

Structure.—The large intestine has four coats—serous, muscular, areolar, and mucous.

The *serous coat* is derived from the peritoneum, and invests the different portions of the large intestine to a variable extent. The cæcum is completely covered by the serous membrane. The ascending and descending colon are usually covered only in front.¹ The transverse colon is almost completely invested, the parts corresponding to the attachment of the great omentum and transverse meso-colon being alone excepted. The sigmoid flexure is nearly completely surrounded, the point corresponding to the attachment of the sigmoid meso-colon being excepted. The upper part of the rectum is almost completely invested by the peritoneum: the middle portion is covered only on its anterior surface, and the lower portion is entirely devoid of any serous covering. In the course of the colon and upper part of the rectum the peritoneal coat is thrown into a number of small pouches filled with fat, called *appendices epiploicæ*. They are chiefly appended to the transverse colon.

The *muscular coat* consists of an external longitudinal and an internal circular layer of muscular fibres.

The *longitudinal fibres*, although found to a certain extent all round the inte-

¹ See foot-note, page 941.

tine, do not form a uniform layer over the whole surface of the large intestine. In the cæcum and colon they are especially collected into three flat longitudinal bands, each being about half an inch in width. These bands commence at the attachment of the appendix vermiformis to the cæcum: one, the posterior, is placed along the attached border of the intestine; the anterior band, the largest, corresponds along the arch of the colon to the attachment of the great omentum, but is in front in the ascending and descending colon and sigmoid flexure; the third, or lateral band, is found on the inner side of the ascending and descending colon and on the under border of the transverse colon. These bands are nearly one-half shorter than the other parts of the intestine, and serve to produce the sacculi which are characteristic of the cæcum and colon; accordingly, when they are dissected off, the tube can be lengthened, and its sacculated character becomes lost. In the sigmoid flexure the longitudinal fibres become more scattered, but upon its lower part and round the rectum they spread out and form a thick uniform layer.

The *circular fibres* form a thin layer over the cæcum and colon, being especially accumulated in the intervals between the sacculi; in the rectum they form a thick layer, especially at its lower end, where they become numerous and form the Internal sphincter.

The *areolar coat* connects the muscular and mucous layers closely together.

The *mucous membrane* in the cæcum and colon is pale, and of a grayish or pale yellow color. It is quite smooth, destitute of villi, and raised into numerous crescentic folds which correspond to the intervals between the sacculi. In the rectum it is thicker, of a darker color, more vascular, and connected loosely to the muscular coat, as in the œsophagus. When the lower part of the rectum is contracted, its mucous membrane is thrown into a number of folds, some of which, near the anus, are longitudinal in direction and are effaced by the distension of the gut. Besides these there are certain permanent folds, of a semilunar shape, known as Houston's valves.¹ They are usually three in number; sometimes a fourth is found, and occasionally only two are present. One is situated near the commencement of the rectum, on the right side; another extends inward from the left side of the tube, opposite the middle of the sacrum; the largest and most constant one projects backward from the fore part of the rectum, opposite the base of the bladder. When a fourth is present, it is situated about an inch above the anus on the back of the rectum. These folds are about half an inch in width, and contain some of the circular fibres of the gut. In the empty state of the intestine they overlap each other, as Mr. Houston remarks, so effectually as to require considerable manœuvring to conduct a bougie or the finger along the canal of the intestine. Their use seems to be "to support the weight of fecal matter, and prevent its urging toward the anus, where its presence always excites a sensation demanding its discharge."

As in the small intestine, the mucous membrane consists of a muscular layer, the *muscularis mucosæ*; of a quantity of retiform tissue, in which the vessels ramify; of a basement membrane and epithelium, which is of the columnar variety and exactly resembles the epithelium found in the small intestine. The mucous membrane of this portion of the bowel presents for examination simple follicles and solitary glands.

The *simple follicles* are minute tubular prolongations of the mucous membrane, arranged perpendicularly, side by side, over its entire surface; they are longer, more numerous, and placed in much closer apposition than those of the small intestine, and they open by minute rounded orifices upon the surface, giving it a cribriform appearance.

The *solitary glands* (Fig. 545) in the large intestine are most abundant in the cæcum and appendix vermiformis, but are irregularly scattered also over the rest of the intestine. They are similar to those of the small intestine.

Vessels and Nerves.—The arteries supplying the large intestine give off large branches, which ramify between the muscular coats, supplying them, and, after dividing into small vessels in the submucous tissue, pass to the mucous membrane.

¹ *Dublin Hosp. Reports*, vol. v. p. 163.

In the lower part of the rectum, however, the arrangement is somewhat different. Here the vessels run in a longitudinal direction, parallel with each other, to the external orifice, where they are joined by large transverse branches. In their course they communicate with each other. The veins of the rectum form an intricate interlacement (the *hæmorrhoidal plexus*), and, pursuing from it a longitudinal course similar to the arteries, empty themselves partly into the internal iliac vein (systemic circulation) and partly into the inferior mesenteric vein (portal circulation). The nerves are derived from the plexuses of the sympathetic nerve around the branches of the superior and inferior mesenteric arteries that are

FIG. 545.—Minute structure of large intestine.

distributed to the large intestine. They are distributed in a similar way as those in the small intestine.

Surface Form.—The coils of the small intestine occupy the front of the abdomen below the transverse colon, and are covered more or less completely by the great omentum. For the most part the coils of the jejunum occupy the left side of the abdominal cavity—*i. e.* the left lumbar and inguinal regions and the left half of the umbilical region—whilst the coils of the ileum are situated to the right, in the right lumbar and inguinal regions, in the right half of the umbilical region, and also the hypogastric. The cæcum is situated in the right inguinal region. Its position varies slightly, but the mid-point of a line drawn from the anterior superior spinous process of the ilium to the symphysis pubis will about mark the middle of its lower border. It is comparatively superficial. From it the ascending colon passes upward through the right lumbar and hypochondriac regions, and becomes more deeply situated as it ascends to the hepatic flexure, which is deeply placed under cover of the liver. The transverse colon crosses the belly transversely on the confines of the umbilical and epigastric regions, its lower border being on a level slightly above the umbilicus, its upper border just below the greater curvature of the stomach. The splenic flexure of the colon is situated behind the stomach in the left hypochondrium, and is on a higher level than the hepatic flexure. The descending colon is deeply seated, passing down through the left hypochondriac and lumbar regions to the sigmoid flexure, which is situated in the left inguinal regions, and which can be felt in thin persons, with relaxed abdominal walls, rolling under the fingers when empty, and when distended forming a distinct tumor.

Surgical Anatomy.—The small intestines are much exposed to injury, but, in consequence of their elasticity and the ease with which one fold glides over another, they are not so frequently ruptured as would otherwise be the case. Any part of the small intestine may be ruptured, but probably the most common situation is the transverse duodenum, on account of its being more fixed than other portions of the bowel, and because it is situated in front of the bodies of the vertebrae, so that if this portion of the abdomen is struck by a sharp blow, as from the kick of a horse, it is unable to glide out of the way, but is compressed against the bone and so lacerated. Wounds of the intestine sometimes occur. If the wound is a small puncture, under it is said three lines in length, no extravasation of the contents of the bowel takes place. The mucous membrane becomes everted and plugs the little opening. The bowels, therefore, may be safely punctured with a fine capillary trocar, in cases of excessive distension of the intestine with gas, without fear of extravasation. A longitudinal wound gapes more than a transverse, owing to the greater amount of circular muscular fibres. The small intestine, and most frequently the ileum, may become strangulated by internal bands, or through apertures, normal or abnormal. The bands may be formed in several different ways: they may be old peritoneal adhesions from

previous attacks of peritonitis; or an adherent omentum from the same cause; or the band may be formed by Meckel's diverticulum, which has contracted adhesions at its distal extremity; or the band may be the result of the abnormal attachment of some normal structure, as the adhesion of two appendices epiploicæ, or an adherent vermiform appendix or Fallopian tube. Intussusception or invagination of the small intestine may take place in any part of the jejunum and ileum, but the most frequent situation is at the ileo-cæcal valve, the valve forming the apex of the entering tube. This form may attain great size, and it is not uncommon in these cases to find the valve projecting from the anus. Stricture, the impaction of foreign bodies, and twisting of the gut (*volvulus*) may lead to intestinal obstruction.

Foreign bodies and small hardened masses of fecal matter are very liable to become lodged in the vermiform appendix. Here they set up inflammation, often cause perforation of the appendix and formation of abscess in the loose connective tissue around. This may require operative interference, and in some cases of recurrent attacks of appendicitis this little diverticulum of the bowel has been removed. In external hernia the ileum is the portion of bowel most frequently herniated. When a part of the large intestine is involved, it is usually the cæcum, and this may occur even on the left side. In some few cases the vermiform appendix has been the part implicated in cases of strangulated hernia, and has given rise to serious symptoms of obstruction. Occasionally ulceration of the duodenal glands may occur in cases of burns, but is not a very common complication. The ulcer may perforate one of the large duodenal vessels, and may cause death from hæmorrhage, or it may perforate the coats of the intestine and produce fatal acute peritonitis. The diameter of the large intestine gradually diminishes from the cæcum, which has the greatest diameter of any part of the bowel, to the point of junction of the sigmoid flexure with the rectum, at or a little below which point stricture most commonly occurs and diminishes in frequency as one proceeds upward to the cæcum. When distended by some obstruction low down, the outline of the large intestine can be defined throughout nearly the whole of its course—all, in fact, except the hepatic and splenic flexures, which are more deeply placed; the distension is most obvious in the two flanks and on the front of the abdomen just above the umbilicus. The cæcum, however, is that portion of the bowel which is, of all, most distended. It sometimes assumes enormous dimensions, and has been known to be perforated from the pressure, causing fatal peritonitis. The hepatic flexure and the right extremity of the transverse colon is in close relationship with the liver, and abscess of this viscus sometimes bursts into the gut in this situation. The gall-bladder may become adherent to the colon, and gall-stones may find their way through into the gut, where they may become impacted or may be discharged per anum. The mobility of the sigmoid flexure renders it more liable to become the seat of a volvulus or twist than any other part of the intestine. It generally occurs in patients who have been the subjects of habitual constipation, and in whom, therefore, the meso-sigmoid flexure is elongated. The gut at this part being loaded with feces, from its weight falls over the gut below, and so gives rise to the twist.

The surgical anatomy of the rectum is of considerable importance. There may be congenital malformation due to arrest or imperfect development. Thus, there may be no inflection of the epiblast (see page 134), and consequently a complete absence of the anus; or the hind-gut may be imperfectly developed, and there may be an absence of the rectum, though the anus is developed; or the inflection of the epiblast may not communicate with the termination of the hind-gut from want of solution of continuity in the septum which in early fetal life exists between the two. The mucous membrane is thick and but loosely connected to the muscular coat beneath, and thus favors prolapse, especially in children. The vessels of the rectum are arranged, as mentioned above, longitudinally, and are contained in the loose cellular tissue between the mucous and muscular coats, and receive no support from surrounding tissues, and this favors varicosity. Moreover, the blood from these vessels is returned into the general circulation through two distinct channels—part through the systemic system and part through the portal system—so that they may be said to be placed between the portal and systemic circulations, and thus predisposed to congestion and consequent dilatation. In addition to this, there are no valves in the superior hæmorrhoidal veins, and the vessels of the rectum are placed in a dependent position, and are liable to be pressed upon and obstructed by hardened feces. The anatomical arrangement, therefore, of the hæmorrhoidal vessels explains the great tendency to the occurrence of piles. Again, the presence of the Sphincter ani is of surgical importance, since it is the constant contraction of this muscle which prevents an ischio-rectal abscess from healing and causes it to become a fistula. Also, the reflex contraction of this muscle is the cause of the severe pain complained of in fissure of the anus. The relations of the peritoneum to the rectum are of importance in connection with the operation of removal of the lower end of the rectum for malignant disease. This membrane gradually leaves the rectum as it descends into the pelvis; first leaving its posterior surface, then the sides, and then the anterior surface to become reflected in the male on to the posterior wall of the bladder, forming the recto-vesical pouch, and in the female on to the posterior wall of the vagina, forming Douglas's pouch. The recto-vesical pouch of peritoneum extends to within three and a half or four inches from the anus, so that it is not safe to remove more than three inches of the entire circumference of the bowel for fear of the risk of opening the peritoneum. When, however, the disease is confined to the posterior surface of the rectum, or extends farther in this direction, a greater amount of the posterior wall of the gut may be removed, as the peritoneum does not extend on this surface to a lower level than five inches from the margin of the anus. The recto-vaginal or Douglas's pouch in the female extends somewhat farther than the recto-vesical pouch of the male, and therefore it is

necessary to remove a less length of the tube in this sex.¹ Upon introducing the finger into the rectum the membranous portion of the urethra can be felt, if an instrument has been introduced into the bladder, exactly in the middle line; behind this the prostate gland can be recognized by its shape and hardness and any enlargement detected; behind the prostate the fluctuating wall of the bladder when full can be felt, and if thought desirable it can be tapped in this situation; on either side and behind the prostate the vesiculæ seminales can be readily felt, especially if enlarged by tubercular disease. Behind, the coccyx is to be felt, and on the mucous membrane one or two of Houston's folds. The ischio-rectal fossæ can be explored on either side, with a view to ascertaining the presence of deep-seated collections of pus. Finally, it will be noted that the finger is firmly gripped by the sphincter for about an inch up the bowel.

By gradual dilatation of the sphincter the whole hand can be introduced into the rectum so as to reach the descending colon. This method of exploration is rarely, however, required for diagnostic purposes.

The colon frequently requires opening in cases of intestinal obstruction, the descending colon being usually the portion of bowel selected for this operation. The operation of colotomy may be performed either without opening the peritoneum by an incision in the loin (lumbar colotomy), or by an opening through the peritoneum (inguinal colotomy). Lumbar colotomy is performed by placing the patient on the side opposite to the one to be operated on, with a firm pillow under the loin. A line is then drawn from the anterior superior to the posterior superior spine of the ilium, and the mid-point of this line (Heath) or half an inch behind the mid-point (Allingham) is taken, and a line drawn vertically upward from it to the last rib. This line represents, with sufficient correctness, the position of the normal colon. An oblique incision four inches in length is now made midway between the last rib and the crest of the ilium, so that its centre bisects the vertical line, and the following parts successively divided: (1) The skin, superficial fascia, with cutaneous vessels and nerves and deep fascia. (2) The posterior fibres of the External oblique and anterior fibres of the Latissimus dorsi. (3) The Internal oblique. (4) The lumbar fascia and the external border of the Quadratus lumborum. The edges of the wound are now to be held apart with retractors, and the transversalis fascia will be exposed. This is to be opened with care, commencing at the posterior angle of the incision. If the bowel is distended, it will bulge into the wound, and no difficulty will be found in dealing with it. If, however, the gut is empty, this bulging will not take place, and the colon will have to be sought for. The guides to it are the lower end of the kidney, which will be plainly felt, and the outer edge of the Quadratus lumborum. The bowel having been found, is to be drawn well up into the wound, and it may be opened at once and the margins of the openings stitched to the skin at the edge of the wound; or, if the case is not an urgent one, it may be retained in this position by two harelip pins passed through the muscular coat, the rest of the wound closed, and the bowel opened in three or four days, when adhesion of the bowel to the edges of the wound has taken place.

Inguinal colotomy is preferred by many surgeons in those cases where there is no urgent obstruction, and where, therefore, there is no necessity to open the bowel at once. The main reason for preferring this operation is that a spur-shaped process of the meso-colon can be formed which prevents any fecal matter finding its way past the artificial anus and becoming lodged on the diseased structures below. The sigmoid flexure being almost entirely surrounded by peritoneum, a coil can be drawn out of the wound and the greater part of its calibre removed, leaving the remainder attached to the meso-colon, which forms a spur, much the same as in an artificial anus caused by sloughing of the gut after a strangulated hernia, and this prevents any fecal matter finding its way from the gut above the opening into that below. The operation is performed by making an incision two or three inches in length from a point one inch internal to the anterior superior spinous process of the ilium, parallel to Poupart's ligament. The various layers of abdominal muscles are cut through, and the peritoneum opened and sewn to the external skin. The sigmoid flexure is now sought for, and pulled out of the wound and fixed by passing a needle threaded with carbolized silk through the meso-colon close to the gut and then through the abdominal wall. The intestine is now sewn to the skin all round, the suture passing only through the serous and muscular coats. The wound is dressed, and on the second to the fourth day, according to the requirements of the case, the protruded coil of intestine is opened and removed with scissors.

THE LIVER.

The **Liver** is a glandular organ of large size, intended mainly for the secretion of the bile, but effecting also important changes in certain constituents of the blood in their passage through the gland. It is situated in the right hypochondriac and epigastric regions, but in the child extends across the epigastrium into the left hypochondrium. It is the largest gland in the body, weighing from three to four pounds (from fifty to sixty ounces avoirdupois). It measures in its transverse diameter from ten to twelve inches, from six to seven in its antero-posterior, and is about three inches thick at the back part of the right lobe, which is the thickest part.

¹ Allingham says one inch less in the female.

Its *upper or diaphragmatic surface* is convex, directed upward and forward, smooth, covered by peritoneum. It is in relation with the under surface of the Diaphragm, and below, to a small extent, with the abdominal parietes. The surface is divided into two unequal lobes, the right and left, by a fold of peritoneum, the *suspensory or broad ligament*. It presents on the left lobe a shallow depression corresponding to the heart.

Its *under or visceral surface* is concave, directed downward and backward, and is in relation with the stomach and duodenum, the hepatic flexure of the colon, and the right kidney and suprarenal capsule. The surface is divided by a longitudinal fissure into a right and left lobe.

The *posterior surface* is rounded and broad over the right lobe, but narrow on the left. It is not covered by peritoneum, and is in contact with the Diaphragm and posterior wall of the abdomen, and is marked off from the upper surface by the line of reflection of the peritoneum from the under surface of the Diaphragm to the upper surface of the liver. On the right lobe this surface, which is here broad, is marked off from the under surface of the liver by the line of reflection of peritoneum from the posterior portion of the Diaphragm on to the liver, which forms the posterior layer of the coronary ligament. In its centre this posterior surface is deeply notched for the vertebral column, and to the right of this it is indented for the inferior vena cava, which is partly embedded in its substance. Close to the right of the vein is a slight depression for the right suprarenal capsule. To the left of the vena cava is the narrow ridge bounding the lobus Spiegelii behind, and to the left of this a groove indicating the position of the oesophageal orifice of the stomach.

The *anterior border* is thin and sharp, and marked opposite the attachment of the longitudinal ligament by a deep notch, and opposite the cartilage of the ninth rib by a second notch for the fundus of the gall-bladder. In adult males this border usually corresponds with the margin of the ribs, but in women and children it usually projects below the ribs.

The *right extremity of the liver* is thick and rounded, whilst the *left* is thin and flattened.

Ligaments.—The ligaments of the liver (Fig. 546) are five in number, four being formed of folds of peritoneum; the fifth, the *ligamentum teres*, is a round

FIG. 546.—The liver. Upper surface.

fibrous cord resulting from the obliteration of the umbilical vein. The ligaments are the longitudinal, two lateral, coronary, and round.

The *longitudinal ligament* (broad, falciform, or suspensory ligament) is a broad and thin antero-posterior peritoneal fold, falciform in shape, its base being directed

forward, its apex backward. It is attached by one margin to the under surface of the Diaphragm and the posterior surface of the sheath of the Right rectus muscle as low down as the umbilicus; by its hepatic margin it extends from the notch on the anterior margin of the liver as far back as its posterior surface. It consists of two layers of peritoneum closely united together. Its anterior free edge contains the round ligament between its layers.

The *lateral ligaments*, two in number, right and left, are triangular in shape. They are formed of two layers of peritoneum united, and extend from the sides of the Diaphragm to the extremities of the posterior surface of the organ. The left is the longer of the two, and lies in front of the œsophageal opening in the Diaphragm.

The *coronary ligament* connects the posterior surface of the liver to the Diaphragm. It is formed by the reflection of the peritoneum from the Diaphragm on to the upper and lower margins of the posterior surface of the organ. The coronary ligament consists of two layers, which are continuous on each side with the lateral ligaments, and in front with the longitudinal ligament. Between the layers a

FIG. 547.—The Liver. Under surface.

large oval space is left uncovered by peritoneum, and is connected to the Diaphragm by firm areolar tissue.

The *round ligament* (Fig. 546) is a fibrous cord resulting from the obliteration of the umbilical vein. It ascends from the umbilicus, in the anterior free margin of the longitudinal ligament, to the notch in the anterior border of the liver, from which it may be traced along the longitudinal fissure on the under surface of the liver as far back as the inferior vena cava.

Fissures (Fig. 547).—Five fissures are seen upon the under and posterior surfaces of the liver, which serve to divide it into five lobes. They are the longitudinal fissure, the fissure of the ductus venosus, the transverse fissure, the fissure for the gall-bladder, and the fissure for the inferior vena cava. They are arranged in the form of the letter A, the apex of the letter corresponding to the posterior surface of the liver, its base to the anterior free border. The connecting bar would represent the transverse fissure; the two converging limbs posterior to this would represent, the *left one* the fissure for the ductus venosus; the *right one* the fissure for the inferior vena cava; the two diverging limbs anterior to the cross-bar would represent the umbilical fissure (*left*) and the fissure for the gall-bladder (*right*).

The *longitudinal fissure* is a deep groove which extends from the notch on the

anterior margin of the liver to the posterior surface of the organ. It separates the right and left lobes; the transverse fissure joins it, at right angles, about one-third from its posterior extremity, and divides it into two parts. The anterior half is called the *umbilical fissure*; it is deeper than the posterior part, and lodges the umbilical vein in the foetus or its remains (the round ligament) in the adult. This fissure is often partially bridged over by a prolongation of the hepatic substance, the *pons hepatis*.

The *fissure of the ductus venosus* is the back part of the longitudinal fissure, and is situated partly on the posterior surface of the liver; it is shorter and shallower than the anterior portion. It lodges in the foetus the ductus venosus, and in the adult a slender fibrous cord, the obliterated remains of that vessel.

The *transverse or portal fissure* is a short but deep fissure, about two inches in length, extending transversely across the under surface of the right lobe, nearer to its posterior surface than its anterior border. It joins, nearly at right angles,

FIG. 548.—Under surface of the liver. (From Ellis.)

with the longitudinal fissure. By the older anatomists this fissure was considered the gateway (*porta*) of the liver; hence the large vein which enters at this point was called the *portal vein*. Besides this vein, the fissure transmits the hepatic artery and nerves and the hepatic duct and lymphatics. At their entrance into the fissure the hepatic duct lies in front and to the right, the hepatic artery to the left, and the portal vein behind and between the duct and artery.

The *fissure for the gall-bladder* (*fossa cystis felleæ*) is a shallow oblong fossa placed on the under surface of the right lobe parallel with the longitudinal fissure. It extends from the anterior free margin of the liver, which is occasionally notched for its reception, to near the right extremity of the transverse fissure.

The *fissure for the inferior vena cava* is a short deep fissure, occasionally a complete canal, which extends obliquely upward from a little behind the right extremity of the transverse fissure on to the posterior surface of the liver, where it joins the fissure for the ductus venosus. On slitting open the inferior vena cava which is contained in it, a deep fossa is seen, at the bottom of which the hepatic veins communicate with this vessel. This fissure is separated from the transverse fissure by the lobus caudatus, and from the longitudinal fissure by the lobulus Spigelii.

Lobes.—The lobes of the liver, like the ligaments and fissures, are five in number—the right lobe, the left lobe, the lobus quadratus, the lobulus Spigelii, and the lobus caudatus.

The *right lobe* is much larger than the left, the proportion between them being as six to one. It occupies the right hypochondrium, and is separated from the left lobe, on its upper surface, by the longitudinal ligament, on its under and posterior surfaces by the longitudinal fissure, and in front by a deep notch. It is of a quadrilateral form, its under surface being marked by three fissures—the transverse fissure, the fissure for the gall-bladder, and the fissure for the inferior vena cava; and by three shallow impressions, one in front (*impressio colica*), for the hepatic flexure of the colon; one behind (*impressio renalis*), for the right kidney, and one internal, between the last-named and the gall-bladder (*impressio duodenalis*), for the second part of the duodenum.

The *left lobe* is smaller and more flattened than the right. It is situated in the epigastric region. Its upper surface is convex; its under surface is concave, and presents a shallow depression for the stomach (*gastric impression*). This is situated in front of the groove for the œsophagus, and is separated from the longitudinal fissure by a well-marked prominence, the *omental tuberosity*, which lies against the small omentum and lesser curvature of the stomach.

The *lobus quadratus*, or square lobe, is situated on the under surface of the right lobe, bounded in front by the free surface of the liver, behind by the transverse fissure, on the right by the fissure of the gall-bladder, and on the left by the umbilical fissure.

The *lobulus Spigelii* projects from the back part of the under surface of the right lobe. It is bounded in front by the transverse fissure, on the right by the fissure for the vena cava, and on the left by the fissure for the ductus venosus.

The *lobus caudatus*, or tailed lobe, is a small elevation of the hepatic substance extending obliquely outward from the base of the lobulus Spigelii to the under surface of the right lobe. It separates the right extremity of the transverse fissure from the commencement of the fissure for the inferior vena cava.

Vessels.—The vessels connected with the liver are also five in number: they are the hepatic artery, the portal vein, the hepatic vein, the hepatic duct, and the lymphatics.

The *hepatic artery* and *portal vein*, accompanied by numerous lymphatics and nerves, ascend to the transverse fissure between the layers of the gastro-hepatic omentum. The *hepatic duct*, lying in company with them, descends from the transverse fissure between the layers of the same omentum. The relative position of the three structures is as follows: The hepatic duct lies to the right, the hepatic artery to the left, and the portal vein behind and between the other two. They are enveloped in a loose areolar tissue, the capsule of Glisson, which accompanies the vessels in their course through the *portal canals* in the interior of the organ.

The *hepatic veins* convey the blood from the liver. They commence in the substance of the liver, in the capillary terminations of the portal vein and hepatic artery; these tributaries, gradually uniting, usually form three large veins, which converge toward the posterior surface of the liver and open into the inferior vena cava, whilst that vessel is situated in the groove at the back part of this organ. Of these three veins, one from the right and another from the left lobe open obliquely into the vena cava, that from the middle of the organ and lobulus Spigelii having a straight course.

The hepatic veins have no cellular investment, consequently their parietes are adherent to the walls of the canals through which they run; so that, on a section of the organ, these veins remain widely open and solitary, and may be easily distinguished from the branches of the portal vein, which are more or less collapsed and always accompanied by an artery and duct. The hepatic veins are destitute of valves.

The *lymphatics* are large and numerous, consisting of a deep and superficial set. They have been already described.

Nerves.—The nerves of the liver are derived from the hepatic plexus of the sympathetic, from the pneumogastric nerves, especially the left, and from the right phrenic.

Structure.—The substance of the liver is composed of lobules held together by an extremely fine areolar tissue, and of the ramifications of the portal vein, hepatic duct, hepatic artery, hepatic veins, lymphatics, and nerves, the whole being invested by a serous and a fibrous coat.

The *serous coat* is derived from the peritoneum, and invests the greater part of the surface of the organ. It is intimately adherent to the fibrous coat.

The *fibrous coat* lies beneath the serous investment and covers the entire surface of the organ. It is difficult of demonstration, excepting where the serous coat is deficient. At the transverse fissure it is continuous with the capsule of Glisson, and on the surface of the organ with the areolar tissue separating the lobules.

The *lobules* form the chief mass of the hepatic substance; they may be seen either on the surface of the organ or by making a section through the gland.

FIG. 549.—Longitudinal section of an hepatic vein. (After Kiernan.)

FIG. 550.—Longitudinal section of a small portal vein and canal. (After Kiernan.)

They are small granular bodies about the size of a millet-seed, measuring from one-twentieth to one-tenth of an inch in diameter. In the human subject their outline is very irregular, but in some of the lower animals (for example, the pig) they are well-defined, and when divided transversely have a polygonal outline. If divided longitudinally they are more or less foliated or oblong. The bases of the lobules are clustered round the smallest radicles (*sublobular*) of the hepatic veins, to which each is connected by means of a small branch which issues from the centre of the lobule (*intralobular*). The remaining part of the surface of each lobule is imperfectly isolated from the surrounding lobules by a thin stratum of areolar tissue in which is contained a plexus of vessels (the *interlobular plexus*) and ducts. In some animals, as the pig, the lobules are completely isolated one from another by this interlobular areolar tissue.

If one of the sublobular veins be laid open, the bases of the lobules may be seen through the thin wall of the vein on which they rest, arranged in the form of a tessellated pavement, the centre of each polygonal space presenting a minute aperture, the mouth of an intralobular vein (Fig. 549).

Microscopic Appearance.—Each lobule is composed of a mass of cells (*hepatic cells*) surrounded by a dense capillary plexus, composed of vessels which penetrate from the circumference to the centre of the lobule, and terminate in a single

straight vein, which runs through its centre, to open at its base into one of the radicles of the hepatic vein. Between the cells are also the minute commencements of the bile-ducts. Therefore in the lobule we have all the essentials of a secreting gland; that is to say: (1) *cells*, by which the secretion is formed; (2) *blood-vessels*, in close relation with the cells, containing the blood from which the secretion is derived; and (3) *ducts*, by which the secretion, when formed, is carried away. Each of these structures will have to be further considered.

(1) The *hepatic cells* are of more or less spheroidal form, but may be rounded, flattened, or many-sided from mutual compression. They vary in size from the $\frac{1}{1000}$ to the $\frac{1}{2000}$ of an inch in diameter. They consist of a honeycomb network (Klein) without any cell-wall, and contain one or sometimes two distinct nuclei. In the nucleus is a highly refracting nucleolus with granules. Embedded in the honeycomb network are numerous yellow particles, the coloring matter of the bile, and oil-globules. The cells adhere together by their surfaces so as to form rows, which radiate from the centre to the circumference of the lobules. As stated above, they are the chief agents in the secretion of the bile.

(2) *The Blood-vessels*.—The blood in the capillary plexus around the liver-cells is brought to the liver principally by the portal vein, but also to a certain extent by the hepatic artery. For the sake of clearness the distribution of the blood derived from the hepatic artery may be considered first.

The *hepatic artery*, entering the liver at the transverse fissure with the portal vein and hepatic duct, ramifies with these vessels through the portal canals. It gives off *vaginal branches* which ramify in the capsule of Glisson, and appear to be destined chiefly for the nutrition of the coats of the large vessels, the ducts, and the investing membranes of the liver. It also gives off *capsular branches* which reach the surface of the organ, terminating in its fibrous coat in stellate plexuses. Finally it gives off *interlobular branches* which form a plexus on the outer side of each lobule, to supply its wall and the accompanying bile-ducts. From this, lobular branches enter the lobule and end in the capillary network between the cells. Some anatomists, however, doubt whether it transmits any blood directly to the capillary network.

The *portal vein* (Fig. 550) also enters at the transverse fissure and runs through the portal canals, enclosed in Glisson's capsule, dividing into branches in its course, which finally break up into a plexus (the *interlobular plexus*) in the interlobular spaces between the lobules. In their course these branches receive the vaginal and capsular veins, corresponding to the vaginal and capsular branches of the hepatic artery (Fig. 550). Thus it will be seen that all the blood carried to the liver by the portal vein and hepatic artery, except perhaps that derived from the interlobular branches of the hepatic artery, directly or indirectly finds its way into the interlobular plexus. From this plexus the blood is carried into the lobule by fine branches which pierce its wall and then converge from the circumference to the centre of the lobule, forming a number of longitudinal vessels which are connected by transverse or horizontal branches (Fig. 551). In the interstices of the network of vessels thus formed are situated, as before said, the liver-cells: and here it is that, the blood being brought into intimate connection with the liver-cells, the bile is secreted. Arrived at the centre of the lobule, all these minute vessels empty themselves into one vein, of considerable size, which runs down the centre of the lobules from apex to base and is called the *intralobular vein*. At the base of the lobule this vein opens directly into the *sublobular vein*, with which the lobule is connected, and which, as before mentioned, is a radicle of the hepatic vein. The sublobular veins, uniting into larger and larger trunks, end at last in the hepatic veins, which do not receive any intralobular veins. Finally, the hepatic veins, as mentioned at page 677, converge to form three large trunks which open into the inferior vena cava, while that vessel is situated in the fissure appropriated to it at the back of the liver.

(3) *The Ducts*.—Having shown how the blood is brought into intimate relation

with the hepatic cells in order that the bile may be secreted, it remains now only to consider the way in which the secretion, having been formed, is carried away.

FIG. 551.—Horizontal section of liver (dog.)

Several views have prevailed as to the mode of origin of the hepatic ducts; it seems, however, to be clear that they commence by little passages which are formed between the cells, and which have been termed *intercellular biliary passages*.

FIG. 552.—Section of liver.

FIG. 553.—A transverse section of a small portal canal and its vessels. (After Kiernan.) 1. Portal vein. 2. Interlobular branches. 3. Vaginal branches. 4. Hepatic duct. 5. Hepatic artery.

ages or *bile-capillaries* (Fig. 552). These passages are merely little channels or interspaces left between the contiguous surfaces of two cells or in the angle where three or more liver-cells meet (Fig. 552), and it seems doubtful whether there is any delicate membrane forming the wall of the space. The channels thus formed radiate to the circumference of the lobule, and, piercing its wall, form a plexus (*interlobular*) between the lobules. From this plexus ducts are derived which pass into the portal canals, become enclosed in Glisson's capsule, and, accompanying the portal vein and hepatic artery (Fig. 553), join with other ducts to form two main trunks, which leave the liver at the transverse fissure, and by their union form the hepatic duct.

THE GALL-BLADDER.

The **Gall-bladder** is the reservoir for the bile; it is a conical or pear-shaped musculo-membranous sac, lodged in a fossa on the under surface of the right lobe of the liver, and extending from near the right extremity of the transverse fissure to the anterior border of the organ. It is about four inches in length, one inch in breadth at its widest part, and holds from eight to ten drachms. It is divided into a fundus, body, and neck. The *fundus*, or broad extremity, is directed downward, forward and to the right, and occasionally projects beyond the anterior border of the liver; the *body* and *neck* are directed upward and backward to the left. The gall-bladder is held in its position by the peritoneum, which, in the majority of cases, passes over its under surface, but the serous membrane occasionally invests the gall-bladder, which is then connected to the liver by a kind of mesentery.

Relations.—The *body of the gall-bladder* is in relation, by its upper surface, with the liver, to which it is connected by areolar tissue and vessels; by its under surface, with the first portion of the duodenum, occasionally the pyloric end of the stomach, and the hepatic flexure of the colon. The *fundus* is completely invested by peritoneum; it is in relation, in front, with the abdominal parietes, immediately below the ninth costal cartilage; behind, with the transverse arch of the colon. The *neck* is narrow, and curves upon itself like the letter **S**; at its point of connection with the cystic duct it presents a well-marked constriction.

When the gall-bladder is distended with bile or calculi, the fundus may be felt through the abdominal parietes, especially in an emaciated subject: the relations of this sac will also serve to explain the occasional occurrence of abdominal biliary fistulae, through which biliary calculi may pass out, and of the passage of calculi from the gall-bladder into the stomach, duodenum, or colon, which occasionally happens.

Structure.—The gall-bladder consists of three coats—serous, fibrous and muscular, and mucous.

The *external or serous coat* is derived from the peritoneum; it completely invests the fundus, but covers the body and neck only on their under surface.

The *fibro-muscular coat* is a thin but strong layer which forms the framework of the sac, consisting of dense fibrous tissue which interlaces in all directions and is mixed with plain muscular fibres which are disposed chiefly in a longitudinal direction, a few running transversely.

The *internal or mucous coat* is loosely connected with the fibrous layer. It is generally tinged with a yellowish-brown color, and is everywhere elevated into minute rugae, by the union of which numerous meshes are formed, the depressed intervening spaces having a polygonal outline. The meshes are smaller at the fundus and neck, being most developed about the centre of the sac. Opposite the neck of the gall-bladder the mucous membrane projects inward in the form of oblique ridges or folds, forming a sort of screw-like valve.

The mucous membrane is covered with columnar epithelium and secretes an abundance of thick viscid mucus; it is continuous through the hepatic duct with the mucous membrane lining the ducts of the liver, and through the ductus communis choledochus with the mucous membrane of the alimentary canal.

The *Biliary Ducts* are the hepatic, the cystic, and the ductus communis choledochus.

The Hepatic Duct.—Two main trunks of nearly equal size issue from the liver at the transverse fissure, one from the right, the other from the left lobe; these unite to form the hepatic duct, which then passes downward and to the right for about an inch and a half between the layers of the lesser omentum, where it joins at an acute angle with the cystic duct, and so forms the ductus communis choledochus. The hepatic duct, as it descends from the transverse fissure of the liver between the two layers of the lesser omentum, lies in company with the hepatic artery and portal vein.

The *cystic duct*, the smallest of the three biliary ducts, is about an inch and a half in length. It passes obliquely downward and to the left from the neck of

the gall-bladder, and joins the hepatic duct to form the common duct. It lies in the gastro-hepatic omentum in front of the vena portæ, the hepatic artery lying to its left side. The mucous membrane lining its interior is thrown into a series of crescentic folds, from five to twelve in number, similar to those found in the neck of the gall-bladder. They project into the duct in regular succession, and are directed obliquely round the tube, presenting much the appearance of a continuous spiral valve. When the duct has been distended the spaces between the folds are dilated so as to give to its exterior a sacculated appearance.

The **ductus communis choledochus**, the largest of the three, is the common excretory duct of the liver and gall-bladder. It is about three inches in length, of the diameter of a goosequill, and formed by the junction of the cystic and hepatic ducts.

It descends along the right border of the lesser omentum behind the first portion of the duodenum, in front of the vena porta, and to the right of the hepatic artery; it then passes between the pancreas and descending portion of the duodenum, and, running for a short distance along the right side of the pancreatic duct near its termination passes with it obliquely between the mucous and muscular coats. The two ducts open by a common orifice upon the summit of a papilla, situated at the inner side of the descending portion of the duodenum, a little below its middle.

Structure.—The coats of the biliary ducts are an external or fibrous and an internal or mucous. The fibrous coat is composed of strong fibro-areolar tissue, with a certain amount of muscular tissue arranged for the most part in a circular manner around the duct. The mucous coat is continuous with the lining membrane of the hepatic ducts and gall-bladder, and also with that of the duodenum, and, like the mucous membrane of these structures, its epithelium is of the columnar variety. It is provided with numerous mucous glands which are lobulated and open by minute orifices scattered irregularly in the larger ducts. In the smaller ducts, which lie in the portal canals in the substance of the liver, are also a number of orifices, disposed in two longitudinal rows, which were formerly regarded as the openings of mucous glands, but which are merely the orifices of tubular recesses. They occasionally anastomose, and from the sides of them saccular dilatations are given off.

Surface Form.—The liver is situated in the right hypochondriac and the epigastric regions, and is moulded to the arch of the Diaphragm. In the greater part of its extent it lies under cover of the lower ribs and their cartilages, but in the epigastric region it comes in contact with the abdominal wall in the subcostal angle. The *upper limit of the right lobe of the liver* may be defined by a line drawn from the articulation of the fifth right costal cartilage to the sternum horizontally outward to a little below the nipple, and then inclined downward to reach the seventh rib at the side of the chest. The *upper limit of the left lobe* may be defined by continuing this line to the left, with an inclination downward as it crosses the gladius, to a point about two inches to the left of the sternum on a level with the sixth left costal cartilage. The *lower limit of the liver* may be indicated by a line drawn half an inch below the lower border of the thorax on the right side as far as the ninth right costal cartilage, and thence obliquely upward across the subcostal angle to the eighth left costal cartilage. A slight curved line with its convexity to the left from this point—i. e. the eighth left costal cartilage—to the termination of the line indicating the upper limit will denote the left margin of the liver. The fundus of the gall-bladder approaches the surface behind the anterior extremity of the ninth costal cartilage, close to the outer margin of the Right rectus muscle.

It must be remembered that the liver is subject to considerable alterations in position, and the student should make himself acquainted with the different circumstances under which this occurs, as they are of importance in determining the existence of enlargement or other diseases of the organ.

Its position varies according to the posture of the body. In the erect position in the adult male the edge of the liver projects about half an inch below the lower edge of the right costal cartilages, and its anterior border can be often felt in this situation if the abdominal wall is thin. In the supine position the liver gravitates backward and recedes above the lower margin of the ribs, and cannot then be detected by the finger. In the prone position it falls forward, and can then generally be felt in a patient with loose and lax abdominal walls. Its position varies also with the ascent or descent of the Diaphragm. In a deep inspiration the liver descends below the ribs; in expiration it is raised behind them. Again, in emphysema, where the lungs are distended and the Diaphragm descends very low, the liver is pushed down; in some other

diseases, as phthisis, where the Diaphragm is much arched, the liver rises very high up. Pressure from without, as in tight-lacing, by compressing the lower part of the chest, displaces the liver considerably, its anterior edge often extending as low as the crest of the ileum; and its convex surface is often at the same time deeply indented from the pressure of the ribs. Again, its position varies greatly according to the greater or less distension of the stomach and intestines. When the intestines are empty the liver descends in the abdomen, but when they are distended it is pushed upward. Its relations to surrounding organs may also be changed by the growth of tumors or by collections of fluid in the thoracic or abdominal cavities.

Surgical Anatomy.—On account of its large size, its fixed position, and its friability, the liver is more frequently ruptured than any of the abdominal viscera. The rupture may vary considerably in extent, from a slight scratch to an extensive laceration completely through its substance, dividing it into two parts. Sometimes an internal rupture without laceration of the peritoneal covering takes place, and such injuries are most susceptible of repair; but small tears of the surface may also heal; when, however, the laceration is extensive, death usually takes place from hæmorrhage, on account of the fact that the hepatic veins are contained in rigid canals in the liver-substance and are unable to contract, and are moreover unprovided with valves. The liver may also be torn by the end of a broken rib perforating the Diaphragm. The liver may be injured by stabs or other punctured wounds, and when these are inflicted through the chest-wall both pleural and peritoneal cavities may be opened up and both lung and liver be wounded. In cases of wound of the liver from the front, hernia of a part of this viscus may take place, but can generally easily be replaced. Abscess of the liver is of not unfrequent occurrence, and may open in many different ways on account of the relations of this viscus to other organs. Thus, it has been known to burst into the lungs, and the pus been coughed up, or into the stomach and the pus vomited; it may burst into the colon or into the duodenum; or, by perforating the Diaphragm, it may empty itself into the pleural cavity. Frequently it makes its way forward and points on the anterior abdominal wall, and finally it may burst into the peritoneal or pericardiac cavities. Abscesses of the liver frequently require opening, and this should be done preferably by an incision in the right semilunar line, in two stages: the peritoneal cavity being opened and the liver over the summit of the abscess being stitched to the parietal peritoneum on the first occasion, and three or four days subsequently the abscess being evacuated. Hydatid cysts are more often found in the liver than in any other of the viscera. The reason of this is not far to seek. The embryo of the egg of the *tænia echinococcus*, being liberated in the stomach by the disintegration of its shell, bores its way through the gastric walls, and usually enters a blood-vessel and is carried by the blood-stream to the hepatic capillaries, where its onward course is arrested, and where it undergoes development into the fully-formed hydatid.

When the *gall-bladder* is ruptured, or one of its main ducts, which may occur independently of laceration of the liver, the injury is necessarily fatal from peritonitis caused by the extravasation of bile into the peritoneal cavity.

The gall-bladder may become distended with bile in cases of obstruction of its duct or the common bile-duct, or from a collection of gall-stones within its interior, thus forming a large tumor. The swelling is pear-shaped, and projects downward and forward to the umbilicus. It moves with respiration, since it is attached to the liver. To relieve this condition the gall-bladder must be opened and the gall-stones removed. The operation is performed by an incision two or three inches long in the right semilunar line, commencing an inch below the costal margin. The peritoneal cavity is opened, and the tumor having been found, sponges are packed round it to protect the peritoneal cavity, and it is aspirated. When the contained fluid has been evacuated the flaccid bladder is drawn out of the abdominal wound and its wall incised to the extent of an inch; any gall-stones in the bladder are now removed and the interior of the sac sponged dry. If the case is one of obstruction of the duct, an attempt must be made to dislodge the stone by manipulation through the wall of the duct, or it must be crushed from without by carefully padded forceps. After all obstruction has been removed a drainage-tube is to be inserted and the external wound closed around it, the stitches being passed through the parietal peritoneum and also through the peritoneum covering the gall-bladder around the incision, so as to bring these two surfaces into apposition. The fistulous opening generally closes in the course of a few weeks.

THE PANCREAS.

Dissection.—The pancreas may be exposed for dissection in three different ways: 1. By raising the liver, drawing down the stomach, and tearing through the gastro-hepatic omentum and the ascending layer of the transverse meso-colon. 2. By raising the stomach, the arch of the colon, and great omentum, and then dividing the inferior layer of the transverse meso-colon and raising the ascending layer of the transverse meso-colon. 3. By dividing the two layers of peritoneum which descend from the great curvature of the stomach to form the great omentum, turning the stomach upward, and then cutting through the ascending layer of the transverse meso-colon (see Fig. 523, page 917).

The **Pancreas** (*πανκρέας*, all flesh) is a compound racemose gland analogous in its structure to the salivary glands, though softer and less compactly arranged than those organs. In shape it is transversely oblong, flattened from before backward, and bears some resemblance to a dog's tongue, its right extremity being

broad and presenting a sort of angular bend from above downward called the *head*, whilst its left extremity gradually tapers to form the *tail*, the intermediate portion being called the *body*. It is situated transversely across the posterior wall of the abdomen, at the back of the epigastric and left hypochondriac regions. Its length varies from six to eight inches, its breadth is an inch and a half, and its thickness from half an inch to an inch, being greater at its right extremity and along its upper border. Its weight varies from two to three and a half ounces, but it may reach six ounces.

The *right extremity* or *head of the pancreas* (Fig. 554) is curved upon itself from above downward, and is embraced by the concavity of the duodenum. The

FIG. 554.—The pancreas and its relations.

common bile-duct descends behind, between the duodenum and pancreas, and the pancreatico-duodenal artery descends in front between the same parts.

The *lesser end* or *tail of the pancreas* is narrow; it extends to the left as far as the spleen, and is placed over the left kidney and suprarenal capsule.

The *body of the pancreas* is somewhat prismatic in shape, and has three surfaces—*anterior*, *posterior*, and *inferior*.

The *anterior surface* is somewhat concave, and is covered by the posterior surface of the stomach, which rests upon it.

The *posterior surface* is separated from the vertebral column by the aorta, vena cava, the commencement of the vena porta, the pillars of the Diaphragm, and the superior mesenteric artery and vein. These latter vessels are surrounded by a lobular fold of the gland which passes transversely to the left behind them, and thus these vessels are embraced by the substance of the gland. This portion is sometimes detached from the rest of the organ, and is called the *lesser pancreas*.

To the left of the vertebral column the posterior surface of the pancreas is in contact with the left renal vessels, the left suprarenal capsule, and the left kidney. Near the upper border of this surface is a groove, running from the centre of the gland to the left, in which is lodged the splenic artery and vein.

The *inferior surface* is narrow, and lies above the third portion of the duodenum, from which it is separated in the middle line by the superior mesenteric vessels, which tilt it somewhat forward. The left extremity of this surface rests on the splenic flexure of the colon.

Projecting above the pancreas, where it crosses the aorta, is the cœliac axis.

The *pancreatic duct*, called the *canal of Wirsung*, from its discoverer, extends transversely from left to right through the substance of the pancreas, nearer to its lower than its upper border, and lying nearer its anterior than its posterior surface. In order to expose it the superficial portion of the gland must be removed. It commences by the junction of the small ducts of the lobules situated in the tail of the pancreas, and, running from right to left, it constantly receives the ducts of the various lobules composing the gland, and, considerably augmented in size, it leaves the head of the pancreas, and, descending slightly, it gets into relation with the common bile-duct, lying to its left side, and, passing very obliquely through the mucous and muscular coats of the duodenum, it terminates by an orifice common to it and the ductus communis choledochus upon the summit of an elevated papilla situated at the inner side of the descending portion of the duodenum, a little below its middle.

Sometimes the pancreatic duct and ductus communis choledochus open separately into the duodenum. The excretory duct of the lesser pancreas is called the *ductus pancreaticus minor*; it opens into the main duct near the duodenum, and sometimes separately into that intestine, at a distance of an inch or more from the termination of the principal duct.

The pancreatic duct, near the duodenum, is about the size of an ordinary quill; its walls are thin, consisting of two coats, an external fibrous and an internal mucous; the latter is thin, smooth, and furnished near its termination with a few scattered follicles.

Sometimes the pancreatic duct is double up to its point of entrance into the duodenum.

In *structure* the pancreas resembles the salivary glands. It differs from them, however, in certain particulars, and is looser and softer in its texture. It is not

FIG. 555.—Transverse section through the middle of the first lumbar vertebra, showing the relations of the pancreas. (Braune.)

enclosed in a distinct capsule, but is surrounded by areolar tissue, which dips down into its interior and connects together the various lobules of which it is composed. Each lobule, like the lobules of the salivary glands, consists of one of the ultimate

ramifications of the main duct, terminating in a number of cæcal pouches or acini. The minute ducts are lined by short columnar epithelium, shorter than that found in the salivary ducts. The acini are wavy and convoluted, and are also lined by columnar cells which present certain characteristics; each cell shows an outer homogeneous or faintly striated portion which becomes deeply stained with dyes and contains the nucleus, and an inner granular portion which does not easily stain. The lumen of the alveolus is hardly visible, being filled with an interstitial substance containing spindle-shaped cells, the *centro-acinar cells of Langerhans*.

Vessels and Nerves.—The *arteries of the pancreas* are derived from the splenic and the pancreatico-duodenal branches of the hepatic and the superior mesenteric. Its *veins* open into the splenic and superior mesenteric veins. Its *lymphatics* terminate in the lumbar glands. Its *nerves* are filaments from the splenic plexus.

Surface Form.—The pancreas lies in front of the first lumbar vertebra, and can sometimes be felt, in emaciated subjects, when the stomach and colon are empty, by making deep pressure in the middle line about three inches above the umbilicus.

Surgical Anatomy.—The pancreas presents but little of surgical importance. It is occasionally the seat of cancer, which usually affects the head or duodenal end, and therefore often speedily involves the common bile-duct, leading to persistent jaundice. Cysts are also occasionally found in it, which may present in the epigastric region, above and to the right of the umbilicus, and may require opening and draining. The fluid in them contains some of the elements of the pancreatic secretion and is very irritating, so that, if allowed to come in contact with the skin of the abdominal wall, it is likely to produce intractable eczema. It has been said that the pancreas is the only abdominal viscus which has never been found in a hernial protrusion; but even this organ has been found, in company with other viscera, in rare cases of diaphragmatic hernia. The pancreas has been known to become invaginated into the intestine, and portions of the organ have sloughed off. In cases of excision of the pylorus great care must be exercised to avoid wounding the pancreas, as the escape of the pancreatic fluid may be attended with serious results. According to Billroth, it is likely, in consequence of its peptonizing qualities, to dissolve the cicatrix of the stomach.

THE SPLEEN.

The **Spleen** was formerly classified, together with the thyroid, thymus, and suprarenal capsules, as one of the ductless or blood-glands. It possesses no excretory duct. It is of an oblong flattened form, soft, of very brittle consistence, highly vascular, of a dark bluish-red color, and situated in the left hypochondriac region, embracing the cardiac end of the stomach. It is invested by peritoneum and connected with the stomach by the gastro-splenic omentum.

Relations.—The *external and posterior surface* is convex, smooth, and in relation with the under surface of the Diaphragm, which separates it from the ninth, tenth, and eleventh ribs of the left side. The *internal surface* is concave, and divided by a vertical fissure, the *hilum*, into an anterior or larger and a posterior or smaller portion. The hilum is pierced by several irregular apertures for the entrance and exit of vessels and nerves. At the margins of the hilum the two layers of peritoneum are reflected from the surface of the spleen on to the cardiac end of the stomach, forming the gastro-splenic omentum, which contains between its layers the splenic vessels and nerves and the vasa brevia. In front of the hilum the internal surface, which is directed somewhat forward, is broad and concave and in contact with the great end of the stomach, and below this with the tail of the pancreas and splenic flexure of the colon. Behind the hilum the internal surface, which is here directed inward, presents a smooth concave fossa which rests on the upper and outer border of the left kidney. The *upper end*, thick and rounded, is in relation with the Diaphragm, to which it is connected by a fold of peritoneum, the *suspensory ligament*. The *lower end* is pointed and rests on the costo-colic ligament. The *anterior margin* is free, rounded, and often notched, especially below.

The spleen is held in its position by two folds of peritoneum: one, the *gastro-splenic omentum*, connects it with the stomach; and the other, the *suspensory*

ligament, with the under surface of the Diaphragm. It is also supported by the costo-colic ligament, upon which its lower end rests (see page 925).

The size and weight of the spleen are liable to very extreme variations at different periods of life, in different individuals, and in the same individual under different conditions. *In the adult*, in whom it attains its greatest size, it is usually about five inches in length, three or four inches in breadth, and an inch or an inch and a half in thickness, and weighs about seven ounces. *At birth* its weight, in proportion to the entire body, is almost equal to what is observed in the adult, being as 1 to 350; whilst in the adult it varies from 1 to 320 and 400. *In old age* the organ not only decreases in weight, but decreases considerably in proportion to the entire body, being as 1 to 700. The size of the spleen is increased during and after digestion, and varies considerably according to the state of nutrition of the body, being large in highly-fed and small in starved animals. In intermittent and other fevers it becomes much enlarged, weighing occasionally from 18 to 20 pounds.

FIG. 556.—Transverse section of the spleen, showing the trabecular tissue and the splenic vein and its branches.

Structure.—The spleen is invested by two coats—an external serous and an internal fibro-elastic coat.

The *external or serous coat* is derived from the peritoneum; it is thin, smooth, and in the human subject intimately adherent to the fibro-elastic coat. It invests almost the entire organ, being reflected from it, at the hilum, on to the great end of the stomach, and at the upper end of the organ on to the Diaphragm.

The *fibro-elastic coat* forms the framework of the spleen. It invests the exterior of the organ, and at the hilum is reflected inward upon the vessels in the form of vaginae or sheaths. From these sheaths, as well as from the inner surface of the fibro-elastic coat, numerous small fibrous bands, *trabeculae* (Fig. 556), are given off in all directions; these, uniting, constitute the areolar framework of the spleen. The framework of the spleen resembles, therefore, a sponge-like material, consisting of a number of small spaces or *areolae*, formed by the trabeculae which are given off from the inner surface of the capsule, or from the sheaths prolonged inward on the blood-vessels. And in these spaces or areolae is contained the *splenic pulp*.

The proper coat, the sheaths of the vessels and the trabeculae, consist of a dense mesh of white and yellow elastic fibrous tissues, the latter considerably predominating. It is owing to the presence of this tissue that the spleen possesses a considerable amount of elasticity, which allows of the very great variations in size that it presents under certain circumstances. In addition to these con-

stituents of this tunic, there is found in man a small amount of non-striped muscular fibre, and in some mammalia (*e. g.* dog, pig, and cat) a very considerable amount, so that the trabeculae appear to consist chiefly of muscular tissue. It is probably owing to this structure that the spleen exhibits, when acted upon by the galvanic current, faint traces of contractility.

The *proper substance of the spleen* or *spleen-pulp* is a soft mass of a dark reddish-brown color, resembling grumous blood. When examined, by means of a thin section, under a microscope, it is found to consist of a number of branching cells and an intercellular substance. The cells are connective-tissue corpuscles, and have been named the *sustentacular* or *supporting cells of the pulp*. The processes of these branching cells communicate with each other, thus forming a delicate reticulated tissue in the interior of the areolae formed by the trabeculae of the capsule; so that each primary space may be considered to be divided into a number of smaller spaces by the junction of these processes of the branching corpuscles. These secondary spaces contain blood, in which, however, the white corpuscles are found to be in larger proportions than they are in ordinary blood. The sustentacular cells are either small uni-nucleated or larger multi-nucleated cells; they do not become deeply stained with carmine, like the cells of the Malpighian bodies, presently to be described (W. Müller), but like them they possess amoeboid movements (Cohnheim). In many of them may be seen deep red or reddish-yellow granules of various sizes which present the characters of the hæmatin of the blood. Sometimes, also, unchanged blood-disks are seen included in these cells, but more frequently blood-disks are found which are altered both in form and color. In fact, blood-corpuscles in all stages of disintegration may be noticed to occur within them. Klein has recently pointed out that sometimes these cells in the young spleen contain a proliferating nucleus; that is to say, the nucleus is of large size, and presents a number of knob-like projections, as if small nuclei were budding from it by a process of gemmation. This observation is of importance, as it may explain one possible source of the colorless blood-corpuscles.

The interspaces or areolae formed by the framework of the spleen are thus filled by a delicate reticulum of branched connective-tissue corpuscles the interstices of which are occupied by blood, and in which the blood-vessels terminate in the manner now to be described.

Blood-vessels of the Spleen.—The splenic artery is remarkable for its large size in proportion to the size of the organ, and also for its tortuous course.

FIG. 557.—Transverse section of the human spleen, showing the distribution of the splenic artery and its branches.

It divides into from four to six branches which enter the hilum of the spleen and ramify throughout its substance (Fig. 557), receiving sheaths from an

involution of the external fibrous tissue. Similar sheaths also invest the nerves and veins.

Each branch runs in the transverse axis of the organ from within outward, diminishing in size during its transit, and giving off in its passage smaller branches, some of which pass to the anterior, others to the posterior part. These ultimately leave the trabecular sheaths, and terminate in the proper substance of the spleen in small tufts or pencils of minute arterioles, which open into the interstices of the reticulum formed by the branched sustentacular cells. Each of the larger branches of the artery supplies chiefly that region of the organ in which the branch ramifies, having no anastomosis with the majority of the other branches.

The *arterioles*, supported by the minute trabeculae, traverse the pulp in all directions in bundles or penicilli of straight vessels. Their external coat, on leaving the trabecular sheaths, consists of ordinary connective tissue, but it gradually undergoes a transformation, becomes much thickened, and is converted into a lymphoid material.¹ This change is effected by the conversion of the connective tissue into a cystogenous tissue, the bundles of connective tissue becoming looser and laxer, their fibrils more delicate, and containing in their interstices an abundance of lymph-corpuscles (W. Müller). This lymphoid material is supplied with blood by minute vessels derived from the artery with which they are in contact, and which terminates by breaking up into a network of capillary vessels.

The altered coat of the arterioles, consisting of lymphoid tissue, presents here and there thickenings of a spheroidal shape, the *Malpighian bodies of the spleen*. These bodies vary in size from about the $\frac{1}{100}$ of an inch to the $\frac{1}{20}$ of an inch in diameter. They are merely local expansions or hyperplasiae of the lymphoid tissue of which the external coat of the smaller arteries of the spleen is formed. They are most frequently found surrounding the arteriole, which thus seems to tunnel them, but occasionally they grow from one side of the vessel only, and present the appearance of a sessile bud growing from the arterial wall. Klein, however, denies this, and says it is incorrect to describe the Malpighian bodies as isolated masses of adenoid tissue, but that they are always formed around an artery, though there is generally a greater amount on one side than the other, and that therefore in transverse sections the artery in the majority of cases is found in an eccentric position. These bodies are visible to the naked eye on the surface of a fresh section of the organ, appearing as minute dots of semi-opaque whitish color in the dark substance of the pulp. In minute structure they resemble the adenoid tissue of lymphatic glands, consisting of a delicate reticulum in the meshes of which lie ordinary lymphoid cells.

FIG. 558.—Part of a Malpighian capsule of the spleen of man. (Klein and Noble Smith.) a. Arterial branch in longitudinal section. b. Adenoid tissue, still containing the lymph-corpuscles; only their nuclei are shown. c. Adenoid reticulum, the lymph-corpuscles accidentally removed.

The reticulum of the tissue is made up of extremely delicate fibrils, and is comparatively open in the centre of the corpuscle, becoming closer at the periphery of the body. The cells which it encloses, like the supporting cells of the pulp, are possessed of amoeboid movements, but when treated with carmine become deeply stained, and can thus easily be recognized from those of the pulp.

The arterioles terminate in capillaries which traverse the pulp in all directions: their walls become much attenuated, lose their tubular character, and the cells of

¹ According to Klein, it is the sheath of the small vessel which undergoes this transformation, and forms a "solid mass of adenoid tissue which surrounds the vessel like a cylindrical sheath" (*Atlas of Histology*, p. 424).

the lymphoid tissue of which they are composed become altered, presenting a branched appearance and acquiring processes which are directly connected with the processes of the sustentacular cells of the pulp (Fig. 559). In this manner the capillary vessels terminate, and the blood flowing through them finds its way into the interstices of the reticulated tissue formed by the branched connective-tissue corpuscles of the splenic pulp. Thus the blood passing through the spleen is

FIG. 559.—Section of spleen, showing the termination of the small blood-vessels.

brought into intimate relation with the elements of the pulp, and no doubt undergoes important changes.

After these changes have taken place the blood is collected from the interstices of the tissue by the rootlets of the veins, which commence much in the same way as the arteries terminate. Where a vein is about to commence the connective-tissue corpuscles of the pulp arrange themselves in rows in such a way as to form an elongated space or sinus. They become changed in shape, being elongated and spindle-shaped, and overlap each other at their extremities. They thus form a sort of endothelial lining of the path or sinus, which is the radicle of a vein. On the outer surface of these cells are seen delicate transverse lines or markings which are due to minute elastic fibrillæ arranged in a circular manner around the sinus. Thus the channel obtains a continuous external investment, and gradually becomes converted into a small vein, which after a time presents a coat of ordinary connective tissue, lined by a layer of fusiform epithelial cells which are continuous with the supporting cells of the pulp. The smaller veins unite to form larger ones which do not accompany the arteries, but soon enter the trabecular sheaths of the capsule, and by their junction form from four to six branches which emerge from the hilum and, uniting, form the splenic vein, the largest radicle of the vena porta.

The veins are remarkable for their numerous anastomoses, while the arteries hardly anastomose at all.

The lymphatics originate in two ways—*i. e.* from the sheaths of the arteries and in the trabeculæ. The former accompany the blood-vessels; the latter pass to the superficial lymphatic plexus which may be seen on the surface of the organ. The two sets communicate in the interior of the organ. They pass through the lymphatic glands at the hilum and terminate in the thoracic duct.

The nerves are derived from branches of the right and left semilunar ganglia and from the right pneumogastric nerve.

Surface Form.—The spleen is situated under cover of the ribs of the left side, being separated from them by the Diaphragm, and above by a small portion of the lower margin of the left lung. Its position corresponds to the ninth, tenth, and eleventh ribs. It is placed very obliquely. "It is oblique in two directions, viz. from above downward and outward, and also from above downward and forward" (Cunningham). "Its highest and lowest points are on a

level respectively with the ninth dorsal and first lumbar spines; its inner end is distant about an inch and a half from the median plane of the body, and its outer end about reaches the mid axillary line" (Quain).

Surgical Anatomy.—Injury of the spleen is less common than that of the liver, on account of its protected situation and connections. It may be ruptured by direct or indirect violence, torn by a broken rib, or injured by a punctured or gunshot wound. When the organ is enlarged the chance of rupture is increased. The great risk is hæmorrhage, owing to the great vascularity of the organ, and the absence of a proper system of capillaries. The injury is not, however, necessarily fatal, and this would appear to be due in a great measure to the contractile power of its capsule, which narrows the wound and prevents the escape of blood. In cases where the diagnosis is clear and the symptoms indicate danger to life laparotomy must be performed; and if the hæmorrhage cannot be stayed by ordinary surgical methods the spleen must be removed. The spleen may become displaced, producing great pain from stretching of the vessels and nerves, and this may require removal of the organ. The spleen may become enormously enlarged in certain diseased conditions, such as ague, syphilis, valvular disease of the heart, or without any obtainable history of previous disease. It may also become enlarged in lymphadenoma as a part of a general blood-disease. In these cases the tumor may sometimes fill the abdomen and extend into the pelvis, and may be mistaken for ovarian or uterine disease.

The spleen is sometimes the seat of cystic tumors, especially hydatids, and of abscess. These cases require treatment by incision and drainage; and in abscess great care must be taken if there are no adhesions between the spleen and abdominal cavity, to prevent the escape of any of the pus into the peritoneal cavity. If possible, the operation should be performed in two stages, as in abscess of the liver. Sarcoma and carcinoma are occasionally found in the spleen, but very rarely as a primary disease.

Extirpation of the spleen has been performed for wounds or injuries, in floating spleen, in simple hypertrophy, and in leukæmic enlargement; but in these latter cases the operation is now regarded as unjustifiable, as every case in which it has been performed has terminated fatally. The incision is best made in the left semilunar line: the spleen is isolated from its surroundings, and the pedicle transfixed and ligatured in two portions, before the tumor is turned out of the abdominal cavity, if this is possible, so as to avoid any traction on the pedicle, which may cause tearing of the splenic vein. In applying the ligature care must be taken not to include the tail of the pancreas, and in lifting out the organ to avoid rupturing the capsule.

THE THORAX.

THE Thorax is a cone-shaped cavity containing and protecting the heart, enclosed in its membranous bag, the *pericardium*, and the lungs, invested by the pleura. Its shape and boundaries have already been described (see page 230).

The Cavity of the Thorax.—The size of the cavity of the thorax does not correspond with its apparent size externally, because (1) the space enclosed by the lower ribs is occupied by some of the abdominal viscera, and (2) the cavity extends above the first rib into the neck. The size of the cavity of the thorax is constantly varying during life with the movements of the ribs and Diaphragm and with the degree of distension of the abdominal viscera. From the collapsed state of the lungs in the dead body it would appear as if the viscera only partly filled the cavity of the thorax, but during life there is no vacant space, that which is seen after death being filled up by the expanded lungs.

The Upper Opening of the Thorax.—The parts which pass through the upper opening of the thorax are, from before backward in the middle line, the Sternohyoid and Sternothyroid muscles, the remains of the thymus gland, the trachea, œsophagus, thoracic duct, and the Longus colli muscle of each side; at the sides, the innominate artery, the left common carotid and left subclavian arteries, the internal mammary and superior intercostal arteries, the right and left innominate veins, and the inferior thyroid veins, the pneumogastric, cardiac, phrenic, and sympathetic nerves, the anterior branch of the first dorsal nerve, and the recurrent laryngeal nerve of the left side. The apex of each lung, covered by the pleura, also projects through this aperture, a little above the margin of the first rib.

The lower opening of the thorax is wider transversely than from before backward. It slopes obliquely downward and backward, so that the cavity of the thorax is much deeper behind than in front. The Diaphragm (see page 446) closes in the opening, forming the floor of the thorax. The floor is flatter at the centre than at the sides, and is higher on the right side than on the left, corresponding in the dead body to the upper border of the fifth costal cartilage on the former, and to the corresponding part of the sixth costal cartilage on the latter. From the highest point on each side the floor slopes suddenly downward to the attachment of the Diaphragm to the ribs; this is more marked behind than in front, so that only a narrow space is left between it and the wall of the thorax.

THE PERICARDIUM.

The **Pericardium** (Figs. 560, 561) is a conical membranous sac in which the heart and the commencement of the great vessels are contained. It is placed behind the sternum and the cartilages of the third, fourth, fifth, sixth, and seventh ribs of the left side, in the interval between the pleuræ.

Its *apex* is directed upward, and surrounds the great vessels about two inches above their origin from the base of the heart. Its *base* is attached to the central tendon and part of the adjoining muscular structure of the Diaphragm, extending a little farther to the left than to the right side. *In front* it is separated from the sternum by the remains of the thymus gland above and a little loose areolar tissue below, and is covered by the margins of the lungs, especially the left. *Behind*, it rests upon the bronchi, the œsophagus, and the descending aorta. *Laterally*, it is covered by the pleuræ, the phrenic nerve with its accompanying vessels descending between the two membranes on either side.

Structure of the Pericardium.—The pericardium is a fibro-serous membrane, and consists, therefore, of two layers, an external fibrous and an internal serous.

The *fibrous layer* is a strong, dense membrane. Above, it surrounds the great vessels arising from the base of the heart, on which it is continued in the form of tubular prolongations which are gradually lost upon their external coat, the strongest being that which encloses the aorta. The pericardium may be traced over these vessels, to become continuous with the deep layer of the cervical fascia. On each side of the ascending aorta it sends upward a diverticulum: the one on

FIG. 560.—Pericardium, from in front. The sac has been distended with plaster. (From a preparation in the Museum of the Royal College of Surgeons.)

the left side, somewhat conical in shape, passes upward and outward, between the arch of the aorta and the pulmonary artery, as far as the ductus arteriosus, where it terminates in a caecal extremity, which is attached by loose connective tissue to the obliterated duct (Fig. 560). The one on the right side passes upward and to the right, between the ascending aorta and vena cava superior, and also terminates in a caecal extremity. Below, the fibrous layer is attached to the central tendon of the Diaphragm, and on the left side to its muscular fibres.

The vessels receiving fibrous prolongations from this membrane are the aorta, the superior vena cava, the right and left pulmonary arteries, and the four pulmonary veins. As the inferior vena cava enters the pericardium through the central tendon of the Diaphragm it receives no covering from the fibrous layer.

The *serous layer* invests the heart, and is then reflected on the inner surface of the pericardium. It consists, therefore, of a visceral and parietal portion. The former invests the surface of the heart and the commencement of the great vessels to the extent of two inches from their origin; from these it is reflected upon the inner surface of the fibrous layer, lining, below, the upper surface of the central tendon of the Diaphragm. The serous membrane encloses the aorta and pulmonary artery in a single tube, but it only partially covers the superior and inferior vena cava and the four pulmonary veins. Its inner surface is smooth and

FIG. 561.—Pericardium, from behind. (From the same preparation as the preceding figure.)

glistening, and secretes a thin fluid which serves to facilitate the movements of the heart.

Arteries of the Pericardium.—These are derived from the internal mammary and its musculo-phrenic branch and from the descending thoracic aorta.

Nerves of the Pericardium.—These are branches from the vagus, the phrenic, and the sympathetic.

The Vestigial Fold of the Pericardium.—In front of the root of the left lung there is a vertical fibrous band, the *vestigial fold of Marshall*. It is formed by the remnant of the lower part of the trunk of the left innominate vein, which after birth became obliterated, between the branch communicating with the right innominate vein and the back of the heart.

Surgical Anatomy.—Paracentesis of the pericardium is sometimes required in cases of effusion into its cavity. The operation is best performed in the fifth intercostal space, one inch to the left of the sternum. The operation has been performed, however, in the fourth, sixth, and seventh spaces, and also on the right side of the sternum.

THE HEART.

The **Heart** is a hollow muscular organ, of a conical form, placed between the lungs and enclosed in the cavity of the pericardium.

Position.—The heart is placed obliquely in the chest: the broad attached end, or base, is directed upward, backward, and to the right, and corresponds to the

FIG. 562.—Front view of the thorax. The ribs and sternum are represented in relation to the lungs, heart and other internal organs. 1. Pulmonary orifice. 2. Aortic orifice. 3. Left auriculo-ventricular orifice. 4. Right auriculo-ventricular orifice.

interval between the fifth and eighth dorsal vertebræ; the apex is directed downward, forward, and to the left, and corresponds to the space between the cartilage of the fifth and sixth ribs, three-quarters of an inch to the inner side, and an inch and a half below the left nipple. The heart is placed behind the lower two-thirds of the sternum, and projects farther into the left than into the right cavity of the chest, extending from the median line about three inches in the former direction, and only one and a half in the latter. The anterior surface of the heart is round and convex, directed upward and forward, and formed chiefly by the right ventricle and part of the left. Its posterior surface is flattened and rests upon the Diaphragm, and is formed chiefly by the left ventricle. The right border is long, thin, and sharp; the left border short, but thick and round.

Size.—The heart in the adult measures five inches in length, three inches and a half in breadth in the broadest part, and two inches and a half in thickness. The prevalent weight, in the male, varies from ten to twelve ounces; in the female, from eight to ten: its proportions to the body being as 1 to 169 in males, 1 to 149 in females. The heart continues increasing in weight, and also in length, breadth, and thickness, up to an advanced period of life: this increase is more marked in men than in women.

Component Parts.—The heart is subdivided by a longitudinal muscular septum into two lateral halves, which are named respectively, from their position, right and left; and a transverse constriction subdivides each half of the organ into two cavities, the upper cavity on each side being called the *auricle*, the lower the *ventricle*. The right is the venous side of the heart, receiving into its auricle the

FIG. 563.—The right auricle and ventricle laid open, the anterior walls of both being removed.

dark venous blood from the entire body, by the superior and inferior vena cava and coronary sinus. From the right auricle the blood passes into the right ventricle, and from the right ventricle, through the pulmonary artery, into the lungs. The blood, arterialized by its passage through the lungs, is returned to the left side of the heart by the pulmonary veins, which open into the left auricle; from the left auricle the blood passes into the left ventricle, and from the left ventricle is distributed, by the aorta and its subdivisions, through the entire body. This constitutes the circulation of the blood in the adult.

The division of the heart into four cavities is indicated by grooves upon its surface. The great transverse groove separating the auricles from the ventricles is called the *auriculo-ventricular groove*. It is deficient, in front, from being crossed by the root of the pulmonary artery. It contains the trunks of the nutrient vessels of the heart. The auricular portion occupies the base of the heart, and is subdivided into two cavities by a median septum. The two ventricles are also separated into a right and left by two longitudinal furrows, the *interventricular grooves*, which are situated one on the anterior, the other on the posterior surface; these extend from the base to the apex of the organ, the former being situated nearer to the left border of the heart, and the latter to the right. It fol-

lows, therefore, that the right ventricle forms the greater portion of the anterior surface of the heart, and the left ventricle more of its posterior surface.

Each of these cavities should now be separately examined.

To examine the interior of the right auricle, an incision should be made along its right border from the entrance of the superior vena cava to that of the inferior. A second cut is to be made from the centre of this first incision to the tip of the auricular appendix, and the flaps raised.

The **Right Auricle** is a little larger than the left, its walls somewhat thinner, measuring about one line, and its cavity is capable of containing about two ounces. It consists of two parts—a principal cavity, or *sinus venosus*, and an *appendix auriculæ*.

The *sinus* is the large quadrangular cavity placed between the two venæ cavae; its walls are extremely thin; it is connected below with the right ventricle, and internally with the left auricle, being free in the rest of its extent.

The *appendix auriculæ*, so called from its fancied resemblance to a dog's ear, is a small conical muscular pouch the margins of which present a dentated edge. It projects from the sinus forward and to the left side, overlapping the root of the aorta.

The internal surface of the right auricle is smooth, except in the appendix and adjacent part of the anterior wall of the sinus venosus, where it is thrown into parallel ridges.

It presents the following parts for examination:

Openings	{	Superior cava.	Valves	{	Eustachian.
		Inferior cava.			Coronary.
		Coronary sinus.			
		Foramina Thebesii.			
		Auriculo-ventricular.			
		Relics of foetal structure	{	Annulus ovalis.	
			{	Fossa ovalis.	
		Musculi pectinati.			
		Tuberculum Loweri.			

The *superior vena cava* returns the blood from the upper half of the body, and opens into the upper and back part of the auricle, the direction of its orifice being downward and forward.

The *inferior vena cava*, larger than the superior, returns the blood from the lower half of the body, and opens into the lowest part of the auricle near the septum, the direction of its orifice being upward and inward. The direction of a current of blood through the superior vena cava would consequently be toward the auriculo-ventricular orifice, whilst the direction of the blood through the inferior cava would be toward the auricular septum. This is the normal direction of the two currents in foetal life.

The *tuberculum Loweri* is a small projection on the right wall of the auricle, between the two venæ cavae. It is most distinct in the hearts of quadrupeds; in man it is scarcely visible. It was supposed by Lower to direct the blood from the superior cava toward the auriculo-ventricular opening.

The *coronary sinus* opens into the auricle, between the inferior vena cava and the auriculo-ventricular opening. It returns the blood from the substance of the heart, and is protected by a semicircular fold of the lining membrane of the auricle, the *coronary valve*. The sinus, before entering the auricle, is considerably dilated—nearly to the size of the end of the little finger. Its wall is partly muscular, and at its junction with the great coronary vein is somewhat constricted and furnished with a valve consisting of two unequal segments.

The *foramina Thebesii* are numerous minute apertures, the mouths of small veins (*venæ cordis minimæ*), which open on various parts of the inner surface of the auricle. They return the blood directly from the muscular substance of the

heart. Some of these foramina are minute depressions in the walls of the heart, presenting a closed extremity.

The *auriculo-ventricular opening* is the large oval aperture of communication between the auricle and the ventricle, to be presently described.

The *Eustachian valve* is situated between the anterior margin of the inferior vena cava and the auriculo-ventricular orifice. It is semilunar in form, its convex margin being attached to the wall of the vein; its concave margin, which is free, terminating in two cornua, of which the left is attached to the anterior edge of the annulus ovalis, the right being lost on the wall of the auricle. The valve is formed by a duplicature of the lining membrane of the auricle containing a few muscular fibres.

In the *fœtus* this valve is of large size, and serves to direct the blood from the inferior vena cava, through the foramen ovale, into the left auricle.

In the *adult* it is occasionally persistent, and may assist in preventing the reflux of blood into the inferior vena cava; more commonly it is small, and its free margin presents a cribriform or filamentous appearance; occasionally it is altogether wanting.

The *coronary valve* (valve of Thebesius) is a semicircular fold of the lining membrane of the auricle, protecting the orifice of the coronary sinus. It prevents the regurgitation of blood into the sinus during the contraction of the auricle. This valve is occasionally double.

The *fossa ovalis* is an oval depression corresponding to the situation of the foramen ovale in the *fœtus*. It is situated at the lower part of the septum auricularum, above and to the left of the orifice of the inferior vena cava.

The *annulus ovalis* is the prominent oval margin of the foramen ovale. It is most distinct above and at the sides; below, it is deficient. A small slit-like valvular opening is occasionally found, at the upper margin of the fossa ovalis, which leads upward beneath the annulus into the left auricle, and is the remains of the aperture between the two auricles in the *fœtus*.

The *musculi pectinati* are small, prominent muscular columns which run across the inner surface of the appendix auriculæ and adjoining portion of the wall of the sinus. They have received the name *pectinati* from the fancied resemblance they bear to the teeth of a comb.

The **Right Ventricle** is triangular in form, and extends from the right auricle to near the apex of the heart. Its anterior or upper surface is rounded and convex, and forms the larger part of the front of the heart. Its under surface is flattened, rests upon the Diaphragm, and forms only a small part of the back of the heart. Its posterior wall is formed by the partition between the two ventricles, the *septum ventriculorum*, the surface of which is convex and bulges into the cavity of the right ventricle. Its upper and inner angle is prolonged into a conical pouch, the *infundibulum* or *conus arteriosus*, from which the pulmonary artery arises. The walls of the right ventricle are thinner than those of the left, the proportion between them being as 1 to 3. The wall is thickest at the base, and gradually becomes thinner toward the apex. The cavity, which equals that of the left ventricle, is capable of containing about three fluidounces.¹

To examine the interior of the right ventricle, an incision should be made a little to the right of the anterior interventricular groove from the pulmonary artery to the apex of the heart, and should be carried up from thence a little to the right of the posterior interventricular groove, as far as the auriculo-ventricular opening.

The following parts present themselves for examination:

Openings	{ Auriculo-ventricular.
	{ Opening of the pulmonary artery.
Valves	{ Tricuspid.
	{ Semilunar.

¹ Marrant Baker says that "taking the means of various estimates, it may be inferred that each ventricle is able to contain four to six ounces of blood" (Kirke's *Physiology*, 10th edition, p. 156).

And a muscular and tendinous apparatus connected with the tricuspid valve:

Columnæ carneæ.

Chordæ tendineæ.

The *auriculo-ventricular orifice* is the large oval aperture of communication between the auricle and ventricle. It is situated at the base of the ventricle, near the right border of the heart. The opening is about an inch in diameter,¹ oval from side to side, surrounded by a fibrous ring, covered by the lining membrane of the heart, and rather larger than the corresponding aperture on the left side, being sufficiently large to admit the ends of four fingers. It is guarded by the tricuspid valve.

The *opening of the pulmonary artery* is circular in form, and situated at the summit of the *conus arteriosus*, close to the *septum ventriculorum*. It is placed on the left side of the auriculo-ventricular opening, upon the anterior aspect of the heart. Its orifice is guarded by the pulmonary semilunar valves.

The *tricuspid valve* consists of three segments of a triangular or trapezoidal shape, formed by a duplicature of the lining membrane of the heart, strengthened by a layer of fibrous tissue, and containing, according to Kurschner and Senac, muscular fibres. These segments are connected by their bases to the auriculo-ventricular orifice, and by their sides with one another, so as to form a continuous annular membrane which is attached round the margin of the auriculo-ventricular opening, their free margins and ventricular surfaces affording attachment to a number of delicate tendinous cords, the *chordæ tendineæ*. The largest and most movable segment is placed toward the left side of the auriculo-ventricular opening, interposed between that opening and the pulmonary artery. Another segment corresponds to the front of the ventricle, and a third to its posterior wall. The central part of each segment is thick and strong; the lateral margins are thin and indented. The *chordæ tendineæ* are connected with the adjacent margins of the principal segments of the valve, and are further attached to each segment in the following manner: 1. Three or four reach the attached margin of each segment, where they are continuous with the auriculo-ventricular tendinous ring. 2. Others, four to six in number, are attached to the central thickened part of each segment. 3. The most numerous and finest are connected with the marginal portion of each segment.

The *columnæ carneæ* are the rounded muscular columns which project from nearly the whole of the inner surface of the ventricle, excepting near the opening of the pulmonary artery, where the wall becomes smooth. They may be classified, according to their mode of connection with the ventricle, into three sets: The first set merely form prominent ridges on the inner surface of the ventricle, being attached by their entire length on one side, as well as by their extremities; the second set are attached by their two extremities, but are free in the rest of their extent; whilst the third set (*musculi papillares*), three or four in number, are attached by one extremity to the wall of the heart, the opposite extremity giving attachment to the *chordæ tendineæ*.

The *semilunar valves*, three in number,² guard the orifice of the pulmonary artery. They consist of three semicircular folds, two anterior (right and left) and one posterior, formed by a duplicature of the lining membrane strengthened by fibrous tissue. They are attached by their convex margins to the wall of the artery at its junction with the ventricle, the straight border being free, and directed

¹ In the *Pathological Transactions*, vol. vi. p. 119, Dr. Peacock has given some careful researches upon the weight and dimensions of the heart in health and disease. He states, as the result of his investigations, that in the healthy adult heart the right auriculo-ventricular aperture has a mean circumference of 54.4 lines, or $4\frac{1}{2}\frac{1}{2}$ inches; the left auriculo-ventricular aperture, a mean circumference of 44.3 lines, or $3\frac{3}{4}\frac{1}{2}$ inches; the pulmonic orifice, of 40 lines, or $3\frac{1}{2}\frac{1}{2}$ inches; and the aortic orifice, of 35.5 lines, or $3\frac{1}{4}\frac{1}{2}$ inches; but the dimensions of the orifices varied greatly in different cases, the auriculo-ventricular aperture having a range of from 45 to 60 lines, and the others in the same proportion.

² The pulmonary semilunar valves have been found to be two in number, instead of three (Dr. Hand, of St. Paul, Minn., in the *North-Western Med. and Surg. Jour.*, July, 1873), and the same variety is more frequently noticed in the aortic semilunar valves.

upward in the course of the vessel, against the sides of which the valve-flaps are pressed during the passage of the blood along the artery. The free margin of each is somewhat thicker than the rest of the valve, is strengthened by a bundle of tendinous fibres, and presents at its middle a small projecting thickened nodule called *corpus Arantii*.¹ From this nodule tendinous fibres radiate through the valve to its attached margin, and these fibres form a constituent part of its substance throughout its whole extent, excepting two narrow lunated portions placed on each side of the nodule immediately behind the free margin; here the valve is thin and formed merely by the lining membrane. During the passage of the blood along the pulmonary artery these valves are pressed against the sides of the cylinder and the course of the blood along the tube is uninterrupted; but during the ventricular diastole, when the current of blood along the pulmonary artery is checked and partly thrown back by its elastic walls, these valves become immediately expanded and effectually close the entrance of the tube. When the valves are closed the lunated portions of each are brought into contact with one another by their opposed surfaces, the three corpora Arantii filling up the small triangular space that would be otherwise left by the approximation of the three semilunar valves.

Between the semilunar valves and the commencement of the pulmonary artery are three pouches or dilatations, one behind each valve. These are the pulmonary sinuses (*sinuses of Valsalva*). Similar sinuses exist between the semilunar valves and the commencement of the aorta; they are larger than the pulmonary sinuses. The blood, in its regurgitation toward the heart, finds its way into these sinuses, and so shuts down the valve-flaps.

In order to examine the interior of the left auricle, make an incision on the posterior surface of the auricle from the pulmonary veins on one side to those on the other, the incision being carried a little way into the vessels. Make another incision from the middle of the horizontal one to the appendix.

The **Left Auricle** is rather smaller than the right; its walls thicker, measuring about one line and a half; it consists, like the right, of two parts, a principal cavity or *sinus* and an *appendix auriculæ*.

The *sinus* is cuboidal in form, and concealed in front by the pulmonary artery and aorta; internally, it is separated from the right auricle by the septum auricularum; behind, it receives on each side the pulmonary veins, being free in the rest of its extent.

The *appendix auriculæ* is somewhat constricted at its junction with the auricle; it is longer, narrower, and more curved than that of the right side, and its margins more deeply indented, presenting a kind of foliated appearance. Its direction is forward and toward the right side, overlapping the root of the pulmonary artery.

The following parts present themselves for examination:

The openings of the four pulmonary veins.

Auriculo-ventricular opening.

Musculi pectinati.

The *pulmonary veins*, four in number, open, two into the right, and two into the left side of the auricle. The two left veins frequently terminate by a common opening. They are not provided with valves.

The *auriculo-ventricular opening* is the large oval aperture of communication between the auricle and ventricle. It is rather smaller than the corresponding opening on the opposite side (see note, page 974).

¹ In former editions, as well as in other text-books on anatomy, these little nodules have been described as fibro-cartilaginous in structure. At my request, Dr. Le Cronier Lancaster, Demonstrator of Anatomy at St. George's Hospital, has investigated this subject, and reports that the "*corpora Arantii*" appear to consist of bundles of interlacing connective-tissue fibres with branched connective-tissue cells, and some few elastic fibres. Occasionally a rounded cell, with indistinct capsule, resembling a cartilage-cell was seen; but there were not many of them. At the free edge of the corpus the structure is denser, there being a larger proportion of fibres to cells than in the central portion. He thinks the structure of the corpus should be put down as fibrous and not fibro-cartilaginous.

The *musculi pectinati* are fewer in number and smaller than on the right side; they are confined to the inner surface of the appendix.

On the inner surface of the septum auricularum may be seen a lunated impression bounded below by a crescentic ridge the concavity of which is turned upward. The depression is just above the fossa ovalis in the right auricle.

To examine the interior of the left ventricle, make an incision a little to the left of the anterior interventricular groove from the base to the apex of the heart, and carry it up from thence, a little to the left of the posterior interventricular groove, nearly as far as the auriculo-ventricular groove.

The **Left Ventricle** is longer and more conical in shape than the right ventricle. It forms a small part of the left side of the anterior surface of the

FIG. 564.—The left auricle and ventricle laid open, the posterior walls of both being removed.

heart, and a considerable part of its posterior surface. It also forms the apex of the heart by its projection beyond the right ventricle. Its walls are much thicker than those of the right side, the proportion being as 3 to 1. They are also thickest in the broadest part of the ventricle, becoming gradually thinner toward the base, and also toward the apex, which is the thinnest part.

The following parts present themselves for examination:

Openings {	Auriculo-ventricular.	Valves {	Mitral.
	Aortic.		Semilunar.
	Chordæ tendineæ.	Columnæ carneæ.	

The *auriculo-ventricular opening* is placed below and to the left of the aortic orifice. It is a little smaller than the corresponding aperture of the opposite side, and, like it, is broader in the transverse than in the antero-posterior diameter. It is surrounded by a dense fibrous ring, covered by the lining membrane of the heart, and guarded by the mitral valves.

The *aortic opening* is a circular aperture in front and to the right side of the auriculo-ventricular, from which it is separated by one of the segments of the mitral valve. Its orifice is guarded by the semilunar valves.

The *mitral valve* is attached to the circumference of the auriculo-ventricular orifice in the same way that the tricuspid valve is on the opposite side. It is formed by a duplicature of the lining membrane strengthened by fibrous tissue, and contains a few muscular fibres. It is larger in size, thicker, and altogether stronger than the tricuspid, and consists of two segments of unequal size. The larger segment is placed in front, between the auriculo-ventricular and aortic orifices, and is said to prevent the filling of the aorta during the distension of the ventricle. Two smaller segments are usually found at the angles of junction of the larger. The mitral valve-flaps are furnished with *chordæ tendineæ*, the mode of attachment of which is precisely similar to that of those on the right side, but they are thicker, stronger, and less numerous.

The *semilunar valves* surround the orifice of the aorta; two are posterior (right and left), and one anterior; they are similar in structure and in their mode of attachment to those of the pulmonary artery. They are, however, larger, thicker, and stronger than those of the right side, the *lunulæ* are more distinct, and the *corpora Arantii* larger and more prominent. Between each valve and the cylinder of the aorta is a deep depression, the *sinus aortici* (sinuses of Valsalva); they are larger than those of the root of the pulmonary artery.

The *columnæ carneæ* admit of a subdivision into three sets, like those upon the right side, but they are smaller, more numerous, and present a dense interlacement, especially at the apex and upon the posterior wall. Those attached by one extremity only, the *musculi papillares*, are two in number, being connected one to

FIG. 565.—Section of the heart, showing the interauricular and interventricular septa.

the anterior, the other to the posterior wall; they are of large size, and terminate by free rounded extremities from which the *chordæ tendineæ* arise.

The septum between the two ventricles is thick, especially below (Fig. 565).

At its upper part it suddenly tapers off and becomes destitute of muscular fibres, consisting only of fibrous tissue covered by two layers of endocardium, and on the right side also covered by one of the flaps of the tricuspid valve. It is continued upward, and forms the septum between the aortic vestibule and the right auricle. It is derived from the lower part of the aortic septum of the fœtus, and an abnormal communication may exist at this part owing to defective development of this septum.

The *Endocardium* is a thin membrane which lines the internal surface of the heart; it assists in forming the valves by its reduplications, and is continuous with the lining membrane of the great blood-vessels. It is a smooth, transparent membrane, giving to the inner surface of the heart its glistening appearance. It is more opaque on the left than on the right side of the heart, thicker in the auricles than in the ventricles, and thickest in the left auricle. It is thin on the muscoli pectinati and on the columnæ carneæ, but thicker on the smooth part of the auricular and ventricular walls and on the tips of the muscoli papillares.

Structure.—The heart consists of muscular fibres and of fibrous rings which serve for their attachment.

The *fibrous rings* surround the auriculo-ventricular and arterial orifices: they are stronger upon the left than on the right side of the heart. The auriculo-ventricular rings serve for the attachment of the muscular fibres of the auricles and ventricles, and also for the mitral and tricuspid valves; the ring on the left side is closely connected by its right margin with the aortic arterial ring. Between these and the right auriculo-ventricular ring is a mass of fibrous tissue, and in some of the larger animals, as the ox and elephant, a nodule of bone.

The fibrous rings surrounding the arterial orifices serve for the attachment of the great vessels and semilunar valves. Each ring receives, by its ventricular margin, the attachment of the muscular fibres of the ventricles; its opposite margin presents three deep semicircular notches, within which the middle coat of the artery (which presents three convex semicircular segments) is firmly fixed, the attachment of the artery to its fibrous ring being strengthened by the thin cellular coat and serous membrane externally and by the endocardium within. It is opposite the margins of these semicircular notches, in the arterial rings, that the endocardium by its reduplication, forms the semilunar valves, the fibrous structure of the ring being continued into each of the segments of the valve at this part. The middle coat of the artery in this situation is thin, and the sides of the vessel are dilated to form the sinuses of Valsalva.

The *muscular structure of the heart* consists of bands of fibres which present an exceedingly intricate interlacement. They are of a deep red color and marked with transverse striæ (page 67).

The muscular fibres of the heart admit of a subdivision into two kinds, those of the auricles and those of the ventricles, which are quite independent of one another.

Fibres of the Auricles.—These are disposed in two layers—a superficial layer common to both cavities, and a deep layer proper to each. The *superficial fibres* are more distinct on the anterior surface of the auricles, across the bases of which they run in a transverse direction, forming a thin, but incomplete layer. Some of these fibres pass into the septum auricularum. The *internal or deep fibres* proper to each auricle consist of two sets, looped and annular fibres. The *looped fibres* pass upward over each auricle, being attached by two extremities to the corresponding auriculo-ventricular rings in front and behind. The *annular fibres* surround the whole extent of the appendices auricularum, and are continued upon the walls of the venæ cavæ and coronary sinus on the right side, and upon the pulmonary veins on the left side, at their connection with the heart. In the appendices they interlace with the longitudinal fibres.

The *fibres of the ventricles* are arranged in an exceedingly complex manner, and the accounts given by various anatomists differ considerably. This is probably due partly to the fact that the various layers of muscular fibre of which the

heart is said to be composed are not independent, but their fibres are interlaced to a considerable extent, and therefore any separation into layers must be to a great extent artificial; and also no doubt partly due to the fact, pointed out by Henle, that there are varieties in the arrangement due to individual differences. If the epicardium (visceral layer of pericardium) and the subjacent fat is removed from a heart which has been subjected to prolonged boiling, so as to dissolve the connective tissues, the superficial fibres of the ventricles will be exposed. They will be seen to commence at the base of the heart, where they are attached to the tendinous rings around the orifices, and to pass obliquely downward toward the apex, with a direction from right to left. At the apex the fibres turn suddenly inward, forming what is called the *vortex*, into the interior of the ventricle. On the back of the heart it will be seen that the fibres pass continuously from one ventricle to the other over the interventricular groove; and the same thing will be noticed on the front of the heart at the upper and lower end of the anterior interventricular groove, but in the middle portion of this groove the fibres passing from one ventricle to the other are interrupted by fibres emerging from the septum along the groove; many of the superficial fibres pass in also at this groove to the septum. The vortex is produced, as stated above, by the sudden turning inward of the superficial fibres in a peculiar spiral manner into the interior of the ventricle. Those fibres which descended on the posterior surface of the heart enter, at the vortex, the left ventricle, and, ascending, form the posterior part of the inner layer of muscular fibres lining this cavity and the right (posterior) musculus papillaris; those fibres which descend on the front of the heart, and which pass to the apex, also pass, at the vortex, into the interior of the ventricle, where they form the remainder of the innermost layer of the ventricle and the left (anterior) musculus papillaris. The fibres forming the inner layer of the wall of the ventricle ascend to be attached to the fibrous rings around the orifices.

By dissection these superficial fibres may be removed as a thin stratum, and it will then be found that the ventricles are made up of oblique fibres superimposed in layers one on the top of another, and assuming gradually a less oblique direction as they pass to the middle of the thickness of the ventricular wall, so that in the centre of the wall the fibres are transverse. Internal to this central transverse layer the fibres become oblique again, but in the opposite direction to the external ones. This division into distinct layers is, however, to a great extent artificial, as the fibres pass across from one layer to another, and have therefore to be divided in the dissection, and the change in the direction of the fibres is very gradual. These oblique fibres commence above at the fibrous rings at the base of the heart, and, descending toward the apex, they enter the septum near its lower end. In the septum the fibres which form the left ventricle may be traced in three directions: 1. Some pass upward to be attached to the central fibro-cartilage. 2. Others pass through the septum to become continuous with the fibres of the right ventricle. 3. The remainder pass through the septum to encircle the ventricle as annular fibres. Of the fibres of the right ventricle, some on entering the septum pass upward to be attached to the central fibro-cartilage; some, entering the septum from behind, pass forward to become continuous with the fibres on the anterior surface of the left ventricle; and others, entering in front, pass backward to join the fibres on the posterior wall of the left ventricle. The septum therefore consists of three varieties of fibres—viz. annular fibres, special to the left ventricle; ascending fibres, derived from both ventricles and ascending through the septum to the central fibro-cartilage; and decussating fibres, derived from the anterior wall of one ventricle and passing to the posterior wall of the other ventricle, or from the posterior wall of the right ventricle and passing to the anterior wall of the left. In addition to these fibres there are a considerable number which appear to encircle both ventricles and which pass across the septum without turning into it.

Vessels and Nerves.—The *arteries* supplying the heart are the left or anterior and right or posterior coronary (page 544).

The *veins* accompany the arteries, and terminate in the right auricle. They are

the anterior, posterior, left and right cardiac veins, the right or small and the left or great coronary sinuses, and the *venæ cordis minimæ* (*venæ Thebesii*) (page 673).

The *lymphatics* terminate in the thoracic and right lymphatic ducts.

The *nerves* are derived from the cardiac plexuses, which are formed partly from the cranial nerves and partly from the sympathetic. They are freely distributed both on the surface and in the substance of the heart, the separate filaments being furnished with small ganglia.

Surface Form.—In order to show the extent of the heart in relation to the front of the chest, draw a line from the lower border of the second left costal cartilage, one inch from the sternum, to the upper border of the third right costal cartilage, half an inch from the sternum. This represents the base-line or upper limit of the organ. Take a point an inch and a half below and three-quarters of an inch internal to the left nipple—that is, about three and a half inches to the left of the median line of the body. This represents the apex of the heart. Draw a line from this apex-point, with a slight convexity downward, to the junction of the seventh right costal cartilage to the sternum. This represents the lower limit of the heart. Join the right extremity of the first line—that is, the base-line—with the right extremity of this line—that is, to the seventh right chondro-sternal joint—with a slight curve outward, so that it projects about an inch and a half from the middle line of the sternum. Lastly, join the left extremity of the base-line and the apex-point by a line curved slightly to the left.

The position of the various orifices is as follows: viz. the pulmonary orifice is situated in the upper angle formed by the articulation of the third left costal cartilage with the sternum; the aortic orifice is a little below and internal to this, behind the left border of the sternum, close to the articulation of the third left costal cartilage to this bone. The left auriculo-ventricular opening is behind the sternum, rather to the left of the median line, and opposite the fourth costal cartilages. The right auriculo-ventricular opening is a little lower, opposite the fourth interspace and in the middle line of the body.

A portion of the area of the heart thus mapped out is uncovered by lung, and therefore gives a dull note on percussion; the remainder, being overlapped by the lung, gives a more or less resonant note. The former is known as the area of superficial cardiac dullness; the latter as the area of deep cardiac dullness. The area of superficial cardiac dullness is included between a line drawn from the centre of the sternum, between the fourth costal cartilages, to the apex of the heart and a line drawn from the same point down the lower third of the middle line of the sternum. Below, this area merges into the dullness which corresponds to the liver. Dr. Latham lays down the following rule as a sufficient practical guide for the definition of the portion of the heart which is uncovered by lung or pleura: "Make a circle of two inches in diameter round a point midway between the nipple and the end of the sternum," that is, the gladiolus.

Peculiarities in the Vascular System of the Fœtus.

The chief peculiarities in the heart of the fœtus are the direct communication between the two auricles through the foramen ovale and the large size of the Eustachian valve. There are also several minor peculiarities. Thus, the position of the heart is vertical until the fourth month, when it commences to assume an oblique direction. Its size is also very considerable as compared with the body, the proportion at the second month being 1 to 50; at birth it is as 1 to 120; whilst in the adult the average is about 1 to 160. At an early period of fetal life the auricular portion of the heart is larger than the ventricular, the right auricle being more capacious than the left; but toward birth the ventricular portion becomes the larger. The thickness of both ventricles is at first about equal, but toward birth the left becomes much the thicker of the two.

The *foramen ovale* is situated at the lower and back part of the septum auricularum, forming a communication between the auricles. It remains as a free oval opening from the time of the formation of the auricular septum (about the eighth week) until the middle period of fetal life. About this period a fold grows up from the posterior wall of the auricle to the left of the foramen ovale, and advances over the opening so as to form a sort of valve, which allows the blood to pass only from the right to the left auricle, and not in the opposite direction.

The *Eustachian valve* is developed from the anterior border of the inferior vena cava at its entrance into the auricle. It is directed upward on the left side of the opening of this vein, and serves to direct the blood from the inferior vena cava through the foramen ovale into the left auricle.

The peculiarities in the arterial system of the fœtus are the communication between the pulmonary artery and the descending aorta by means of the *ductus*

arteriosus, and the communication between the internal iliac arteries and the placenta by means of the umbilical arteries.

The *ductus arteriosus* is a short tube, about half an inch in length at birth, and of the diameter of a goosequill. In the early condition it forms the continuation of the pulmonary artery, and opens into the descending aorta just below the origin of the left subclavian artery, and so conducts the chief part of the blood from the right ventricle into this vessel. When the branches of the pulmonary artery have become larger relatively to the ductus arteriosus, the latter is chiefly connected to the left pulmonary artery; and the fibrous cord, which is all that remains of the ductus arteriosus in later life, will be found to be attached to the root of that vessel.

The *umbilical or hypogastric arteries* arise from the internal iliacs, in addition to the branches given off from those vessels in the adult. Ascending along the sides of the bladder to its fundus, they pass out of the abdomen at the umbilicus, and are continued along the umbilical cord to the placenta, coiling round the umbilical vein. They return to the placenta the blood which has circulated in the system of the foetus.

The peculiarity in the venous system of the foetus is the communication established between the placenta and the liver and portal vein through the umbilical vein, and the inferior vena cava through the ductus venosus.

FŒTAL CIRCULATION.

The blood destined for the nutrition of the foetus is carried from the placenta to the foetus, along the umbilical cord, by the umbilical vein. The umbilical vein enters the abdomen at the umbilicus, and passes upward along the free margin of the suspensory ligament of the liver to the under surface of that organ, where it gives off two or three branches to the left lobe, one of which is of large size, and others to the lobus quadratus and lobulus Spigelii. At the transverse fissure it divides into two branches: of these, the larger is joined by the portal vein and enters the right lobe; the smaller branch continues onward, under the name of the ductus venosus, and joins the left hepatic vein at the point of junction of that vessel with the inferior vena cava. The blood, therefore, which traverses the umbilical vein reaches the inferior vena cava in three different ways: the greater quantity circulates through the liver with the portal venous blood before entering the vena cava by the hepatic veins; some enters the liver directly, and is also returned to the inferior cava by the hepatic veins; the smaller quantity passes directly into the vena cava by the junction of the ductus venosus with the left hepatic vein.

In the inferior cava the blood carried by the ductus venosus and hepatic veins becomes mixed with that returning from the lower extremities and viscera of the abdomen. It enters the right auricle, and, guided by the Eustachian valve, passes through the foramen ovale into the left auricle, where it becomes mixed with a small quantity of blood returned from the lungs by the pulmonary veins. From the left auricle it passes into the left ventricle, and from the left ventricle into the aorta, by means of which it is distributed almost entirely to the head and upper extremities, a small quantity being probably carried into the descending aorta. From the head and upper extremities the blood is returned by the branches of the superior vena cava to the right auricle, where it becomes mixed with a small portion of the blood from the inferior cava. From the right auricle it descends over the Eustachian valve into the right ventricle, and from the right ventricle passes into the pulmonary artery. The lungs of the foetus being solid and almost impervious, only a small quantity of the blood of the pulmonary artery is distributed to them by the right and left pulmonary arteries, and is returned by the pulmonary veins to the left auricle; the greater part passes through the ductus arteriosus into the commencement of the descending aorta, where it becomes mixed with a small quantity of blood transmitted by the left ventricle into the aorta.

Along this vessel it descends to supply the lower extremities and viscera of the abdomen and pelvis, the chief portion being, however, conveyed by the umbilical arteries to the placenta.

From the preceding account of the circulation of the blood in the foetus it will be seen—

1. That the placenta serves the double purpose of a respiratory and nutritive

FIG. 556.—Plan of the fetal circulation. In this plan the figured arrows represent the kind of blood, as well as the direction which it takes in the vessels. Thus, arterial blood is figured $\gg \cdots \cdots \rightarrow$; venous blood $\gg \cdots \cdots \leftarrow$; mixed (arterial and venous) blood, $\gg \cdots \cdots \rightarrow$.

organ, receiving the venous blood from the foetus, and returning it again re-oxygenated and charged with additional nutritive material.

2. That nearly the whole of the blood of the umbilical vein traverses the liver

before entering the inferior cava; hence the large size of this organ, especially at an early period of foetal life.

3. That the right auricle is the point of meeting of a double current, the blood in the inferior cava being guided by the Eustachian valve into the left auricle, whilst that in the superior cava descends into the right ventricle. At an early period of foetal life it is highly probable that the two streams are quite distinct, for the inferior cava opens almost directly into the left auricle, and the Eustachian valve would exclude the current along the vein from entering the right ventricle. At a later period, as the separation between the two auricles becomes more distinct, it seems probable that some mixture of the two streams must take place.

4. The blood carried from the placenta to the foetus by the umbilical vein, mixed with the blood from the inferior cava, passes almost directly to the arch of the aorta, and is distributed by the branches of that vessel to the head and upper extremities; hence the large size and perfect development of those parts at birth.

5. The blood contained in the descending aorta, chiefly derived from that which has already circulated through the head and limbs, together with a small quantity from the left ventricle, is distributed to the lower extremities; hence the small size and imperfect development of these parts at birth.

CHANGES IN THE VASCULAR SYSTEM AT BIRTH.

At birth, when respiration is established, an increased amount of blood from the pulmonary artery passes through the lungs, which now perform their office as respiratory organs, and at the same time the placental circulation is cut off. The foramen ovale becomes gradually closed by about the tenth day after birth; the valvular fold above mentioned becomes adherent to the margins of the foramen for the greater part of its circumference, but above a slit-like opening is left between the two auricles which sometimes remains persistent.

The *ductus arteriosus* begins to contract immediately after respiration is established, becomes completely closed from the fourth to the tenth day, and ultimately degenerates into an impervious cord which serves to connect the left pulmonary artery to the descending aorta.

Of the *umbilical* or *hypogastric arteries*, the portion continued on to the bladder from the trunk of the corresponding internal iliac remains pervious as the superior vesical artery, and the part between the fundus of the bladder and the umbilicus becomes obliterated between the second and fifth days after birth, and projects into the peritoneal sac so as to form the two fossae of the peritoneum spoken of in the section on the surgical anatomy of direct inguinal hernia.

The *umbilical vein* and *ductus venosus* become completely obliterated between the second and fifth days after birth, and ultimately dwindle to fibrous cords, the former becoming the round ligament of the liver, the latter the fibrous cord, which in the adult may be traced along the fissure of the ductus venosus.

THE ORGANS OF VOICE AND RESPIRATION.

THE LARYNX.

THE Larynx is the organ of voice, placed at the upper part of the air-passage. It is situated between the trachea and base of the tongue, at the upper and fore part of the neck, where it forms a considerable projection in the middle line. On either side of it lie the great vessels of the neck; behind, it forms part of the boundary of the pharynx, and is covered by the mucous membrane lining that cavity.

The larynx is broad above, where it presents the form of a triangular box, flattened behind and at the sides, and bounded in front by a prominent vertical ridge. Below, it is narrow and cylindrical. It is composed of cartilages which are connected together by ligaments and moved by numerous muscles; the interior is lined by mucous membrane and supplied with vessels and nerves.

The **Cartilages of the Larynx** are nine in number, three single and three pairs:

Thyroid.	Two Arytenoid.
Cricoid.	Two Cornicula Laryngis.
Epiglottis.	Two Cuneiform.

The **Thyroid** (*θυρεός*, a shield) is the largest cartilage of the larynx. It consists of two lateral lamellæ or alæ, united at an acute angle in front, forming a vertical projection in the middle line which is prominent above and called the *pomum Adami*. This projection is subcutaneous, more distinct in the male than in the female, and occasionally separated from the integument by a bursa mucosa.

Each lamella is quadrilateral in form. Its *outer surface* presents an oblique ridge which passes downward and forward from a tubercle situated near the root of the superior cornu. This ridge gives attachment to the Sternothyroid and Thyro-hyoid muscles, and the portion of cartilage included between it and the posterior border, to part of the Inferior constrictor muscle.

The *inner surface* of each ala is smooth, slightly concave, and covered by mucous membrane above and behind; but in front, in the receding angle formed by their junction, are attached the epiglottis, the true and false vocal cords, the Thyro-arytenoid and Thyro-epiglottidean muscles.

FIG. 367. —Side view of the thyroid and cricoid cartilages.

The *upper border of the thyroid cartilage* is sinuously curved, being concave at its posterior part, just in front of the superior cornu, then rising into a convex outline, which dips in front to form the sides of a notch in the middle line immediately above the *pomum Adami*. This border gives attachment throughout its whole extent to the thyro-hyoid membrane.

The *lower border* is connected to the cricoid cartilage, in the median line, by the crico-thyroid membrane, and on each side by the Crico-thyroid muscle.

The *posterior borders*, thick and rounded, terminate above in the *superior cornua*, and below in the *inferior cornua*. The two superior cornua are long and narrow, directed upward, backward, and inward, and terminate in a conical extremity which gives attachment to the thyro-hyoid ligament. The two inferior cornua are short and thick; they pass downward, with a slight inclination forward and inward, and present on their inner surfaces a small oval articular facet for articulation with the side of the cricoid cartilage. The posterior border receives the insertion of the Stylo-pharyngeus and Palato-pharyngeus muscles on each side.

The **Cricoid Cartilage** is so called from its resemblance to a signet-ring (*xyxos*, a ring). It is smaller, but thicker and stronger, than the thyroid cartilage, and forms the lower and back part of the cavity of the larynx.

Its *anterior half* is narrow, convex, affording attachment in front and at the sides to the Crico-thyroid muscles, and behind to part of the Inferior constrictor.

Its *posterior half* is very broad both from side to side and from above downward; it presents in the middle line a vertical ridge for the attachment of the longitudinal fibres of the œsophagus, and on either side a broad depression for the Crico-arytenoideus posticus muscle.

At the point of junction of the two halves of the cartilage on either side is a small round elevation for articulation with the inferior cornu of the thyroid cartilage.

The *lower border of the cricoid cartilage* is horizontal and connected to the upper ring of the trachea by fibrous membrane.

Its *upper border* is directed obliquely upward and backward, owing to the great depth of its posterior surface. It gives attachment in front to the crico-thyroid membrane; at the sides, to part of the same membrane and to the lateral Crico-arytenoid muscle; behind, the highest point of the upper border is surmounted on each side by a smooth oval surface for articulation with the arytenoid cartilage. Between the articular surfaces is a slight notch for the attachment of part of the Arytenoideus muscle.

The *inner surface of the cricoid cartilage* is smooth and lined by mucous membrane.

FIG. 568.—The cartilages of the larynx. Posterior view.

The **Arytenoid Cartilages** are so called from the resemblance they bear, when approximated, to the mouth of a pitcher (*ἀπόρτανα*, a pitcher). They are two in number, and situated at the upper border of the cricoid cartilage, at the back of the larynx. Each cartilage is pyramidal in form, and presents for examination three surfaces, a base, and an apex.

The *posterior surface* is triangular, smooth, concave, and gives attachment to the Arytenoid muscle.

The *anterior surface*, somewhat convex and rough, gives attachment to the Thyro-arytenoid muscle and to the false vocal cord.

The *internal surface* is narrow, smooth, and flattened, covered by mucous membrane, and lies almost in apposition with the cartilage of the opposite side.

The *base* of each cartilage is broad, and presents a concave smooth surface for articulation with the cricoid cartilage. Of its three angles, the *external* is short, rounded, and prominent, receiving the insertion of the Posterior and Lateral crico-arytenoid muscles. The *anterior angle*, also prominent, but more pointed, gives attachment to the true vocal cord. This angle is sometimes called the *vocal process*.

The *apex* of each cartilage is pointed, curved backward and inward, and surmounted by a small, cone-shaped, cartilaginous nodule, the *corniculum laryngis*.

The **cornicula laryngis** (*cartilages of Santorini*) are two small, conical nodules, consisting of yellow fibro-cartilage, which articulate with the summit of the arytenoid cartilages and serve to prolong them backward and inward. To them are attached the aryteno-epiglottidean folds. They are sometimes united to the arytenoid cartilages.

The **cuneiform cartilages** (*cartilages of Wrisberg*) are two small, elongated, cartilaginous bodies, placed one on each side, in the fold of mucous membrane which extends from the apex of the arytenoid cartilage to the side of the epiglottis (*aryteno-epiglottidean fold*); they give rise to small whitish elevations on the inner surface of the mucous membrane, just in front of the arytenoid cartilages.

The **epiglottis** is a thin lamella of fibro-cartilage, of a yellowish color, shaped like a leaf, and placed behind the tongue, in front of the superior opening of the larynx. During respiration its direction is vertically upward, its free extremity curving forward toward the base of the tongue; but when the larynx is drawn up beneath the base of the tongue during deglutition it is carried downward and backward so as to completely close the opening of the larynx. Its free extremity is broad and rounded; its attached end is long and narrow, and connected to the receding angle between the two alae of the thyroid cartilage, just below the median notch, by a long, narrow, ligamentous band, the *thyro-epiglottic ligament*. It is also connected to the posterior surface of the body of the hyoid bone by an elastic ligamentous band, the *hyo-epiglottic ligament*.

Its *anterior or lingual surface* is curved forward toward the tongue, and covered at its upper part by mucous membrane, which is reflected on to the sides and base of the organ, forming a median and two lateral folds, the *glosso-epiglottidean ligaments*.

Its *posterior or laryngeal surface* is smooth, concave from side to side, concavo-convex from above downward, and covered by mucous membrane; when this is removed the surface of the cartilage is seen to be studded with a number of small mucous glands which are lodged in little pits upon its surface. To its sides the aryteno-epiglottidean folds are attached.

Structure.—The cornicula laryngis, cuneiform cartilages, and epiglottis are composed of yellow fibro-cartilage which shows little tendency to calcification, but the other cartilages resemble in structure the costal cartilages, becoming more or less calcified in old age.

Ligaments.—The ligaments of the larynx are *extrinsic*—i. e. those connecting the thyroid cartilage and epiglottis with the hyoid bone, and the cricoid cartilage with the trachea; and *intrinsic*—those which connect the several cartilages of the larynx to each other.

The ligaments connecting the thyroid cartilage with the hyoid bone are three in number—the thyro-hyoid membrane, and the two lateral thyro-hyoid ligaments.

The *thyro-hyoid membrane* is a broad, fibro-elastic, membranous layer, attached below to the upper part of the posterior surface of the thyroid cartilage, and above to the upper border of the hyoid bone, passing behind the posterior surface, and being separated from it by a synovial bursa. It is thicker in the middle line than at either side, in which situation it is pierced by the superior laryngeal vessels and nerve.

The *two lateral thyro-hyoid ligaments* are rounded elastic cords which pass between the superior cornua of the thyroid cartilage and the extremities of the greater cornua of the hyoid bone. A small cartilaginous nodule (*cartilago triticea*), sometimes bony, is frequently found in each.

The ligament connecting the epiglottis with the hyoid bone is the hyo-epiglottic. In addition to this extrinsic ligament, the epiglottis is connected to the tongue by the three glosso-epiglottidean folds of mucous membrane, which may also be considered as extrinsic ligaments of the epiglottis.

The *hyo-epiglottic ligament* is an elastic fibrous band which extends from the anterior surface of the epiglottis, near its apex, to the upper border of the body of the hyoid bone.

The ligaments connecting the thyroid cartilage to the cricoid are also three in number—the crico-thyroid membrane and the capsular ligaments.

The *crico-thyroid membrane* is composed mainly of yellow elastic tissue. It is of triangular shape, thick in front, where it connects together the contiguous margins of the thyroid and cricoid cartilages; thinner at each side, where it extends from the superior border of the cricoid cartilage to the inferior margin of the true vocal cords, with which it is closely united in front.

The anterior portion of the crico-thyroid membrane is convex, concealed on each side by the Crico-thyroid muscle, subcutaneous in the middle line, and crossed horizontally by a small anastomotic arterial arch formed by the junction of the two crico-thyroid arteries.

The lateral portions are lined internally by mucous membrane, and covered by the lateral Crico-arytenoid and Thyro-arytenoid muscles.

A *capsular ligament* encloses the articulation of the inferior cornu of the thyroid with the cricoid cartilage on each side. The articulation is lined by synovial membrane.

The ligaments connecting the arytenoid cartilages to the cricoid are two *capsular ligaments* and two *posterior crico-arytenoid ligaments*. The *capsular crico-arytenoid ligaments* are thin and loose capsules attached to the margin of the articular surfaces; they are lined internally by synovial membrane. The *posterior crico-arytenoid ligaments* extend from the cricoid to the inner and back part of the base of the arytenoid cartilage.

The ligament connecting the epiglottis with the thyroid cartilage is the thyro-epiglottic.

The *thyro-epiglottic ligament* is a long, slender, elastic cord which connects the apex of the epiglottis with the receding angle of the thyroid cartilage immediately beneath the median notch, above the attachment of the vocal cords.

The *crico-tracheal ligament* connects the cricoid cartilage with the first ring of the trachea. It resembles the fibrous membrane which connects the cartilaginous rings of the trachea to each other.

Interior of the Larynx.—The *superior aperture of the larynx* (Fig. 569) is a triangular or cordiform opening, wide in front, narrow behind, and sloping obliquely downward and backward. It is bounded in front by the epiglottis, behind by the apices of the arytenoid cartilages and the cornicula laryngis, and laterally by a fold of mucous membrane enclosing ligamentous and muscular fibres, stretched between the sides of the epiglottis and the apex of the arytenoid cartilages: these are the *aryteno-epiglottidean folds*, on the margins of which the cuneiform cartilages form a more or less distinct whitish prominence.

The *cavity of the larynx* extends from the superior aperture to the lower border of the cricoid cartilage. It is divided into two parts by the projection inward of the vocal cords; between the two cords is a long and narrow triangular fissure or chink, the *rima glottidis*. The portion of the cavity of the larynx above the true vocal cords is broad and triangular in shape, and corresponds to the interval between the alæ of the thyroid cartilage; it contains the false vocal cords, and between these and the true vocal cords are the ventricles of the larynx. The portion below the true vocal cords is at first of an elliptical, and lower down of a circular, form.

The *rima glottidis* is the narrow fissure or chink between the inferior or true

FIG. 569.—The larynx and adjacent parts, seen from above.

vocal cords. It is the narrowest part of the cavity of the larynx, and corresponds to the lower level of the arytenoid cartilages. Its length in the male measures rather less than an inch, its breadth when dilated varying at its widest part from a third to half an inch. In the female these measurements are less by two or three lines. The form of the rima glottidis varies. In its half-closed condition it is a narrow fissure, a little enlarged and rounded behind. In quiet breathing it is widely open, somewhat triangular, the base of the triangle directed backward, and corresponding to the space between

the separated arytenoid cartilages. In forcible expiration it is smaller than during inspiration. When sound is produced it is more narrowed, the margins of the arytenoid cartilages being brought into contact and the edges of the vocal cords approximated and made parallel, the degree of approximation and tension corresponding to the height of the note produced.¹

The *superior or false vocal cords*, so called because they are not directly concerned in the production of the voice, are two folds of mucous membrane enclosing a delicate narrow fibrous band, the *superior thyro-arytenoid ligament*. This ligament consists of a thin band of elastic tissue, attached in front to the angle of the thyroid cartilage below the epiglottis, and behind to the anterior surface of the arytenoid cartilage. The lower border of this ligament, enclosed in mucous membrane, forms a free crescentic margin, which constitutes the upper boundary of the ventricle of the larynx.

The *inferior or true vocal cords*, so called from their being concerned in the production of sound, are two strong fibrous bands (*inferior thyro-arytenoid ligaments*), covered on their surface by a thin layer of mucous membrane. Each ligament consists of a band of yellow elastic tissue, attached in front to the depression between the two alæ of the thyroid cartilage, and behind to the anterior angle of the base of the arytenoid. Its lower border is continuous with the thin lateral part of the crico-thyroid membrane. Its upper border forms the lower boundary of the ventricle of the larynx. Externally, the Thyro-arytenoideus muscle lies parallel with it. It is covered internally by mucous membrane, which is extremely thin and closely adherent to its surface.

The *ventricle of the larynx* is an oblong fossa situated between the superior and inferior vocal cords on each side, and extending nearly their entire length.

¹ On the shape of the rima glottidis in the various conditions of breathing and speaking, see Czerniak, *On the Laryngoscope*, translated for the New Sydenham Society.

This fossa is bounded above by the free crescentic edge of the superior vocal cord, below by the straight margin of the true vocal cord, externally by the corresponding Thyro-arytenoideus muscle. The anterior part of the ventricle leads up by a narrow opening into a caecal pouch of mucous membrane of variable size called the *laryngeal pouch*.

The *sacculus laryngis*, or laryngeal pouch, is a membranous sac placed between the superior vocal cord and the inner surface of the thyroid cartilage, occasionally extending as far as its upper border; it is conical in form, and curved slightly backward like a Phrygian cap. On the surface of its mucous membrane are the openings of sixty or seventy small follicular glands which are lodged in the submucous areolar tissue. This sac is enclosed in a fibrous capsule continuous below with the superior thyro-arytenoid ligament; its laryngeal surface is covered by the Aryteno-epiglottideus inferior muscle (*Compressor sacculi laryngis*, Hilton), whilst its exterior is covered by the Thyro-arytenoideus and Thyro-epiglottideus muscles. These muscles compress the sacculus laryngis and discharge the secretion it contains upon the chordæ vocales, the surfaces of which it is intended to lubricate.

Muscles.—The intrinsic muscles of the larynx are nine in number, six of which are the muscles of the vocal cords and rima glottidis, and three are connected with the epiglottis.

The six muscles of the vocal cords and rima glottidis are—the

Crico-thyroid.	Arytenoideus.
Crico-arytenoideus posticus.	Thyro-arytenoideus.
Crico-arytenoideus lateralis.	Arytenoideus rectus.

The *Crico-thyroid* is triangular in form, and situated at the fore part and side of the cricoid cartilage. It arises from the front and lateral part of the cricoid cartilage; its fibres diverge, passing obliquely upward and outward to be inserted into the lower border of the thyroid cartilage and into the anterior border of the lower cornua.

The inner borders of these two muscles are separated in the middle line by a triangular interval occupied by the crico-thyroid membrane.

The *Crico-arytenoideus posticus* arises from the broad depression occupying each lateral half of the posterior surface of the cricoid cartilage; its fibres pass upward and outward, converging to be inserted into the outer angle of the base of the arytenoid cartilage. The upper fibres are nearly horizontal, the middle oblique, and the lower almost vertical.¹

¹ Dr. Merkel of Leipsic has described a muscular slip which occasionally extends between the outer border of the posterior surface of the cricoid cartilage and the posterior margin of the inferior cornu of the thyroid; this he calls the "*Musculus kerato-cricoideus*." It is not found in every larynx, and when present exists usually only on one side, but is occasionally found on both sides. Sir William Turner (*Edinburgh Medical Journal*, Feb., 1860) states that it is found in about one case in five. Its action is to fix the lower horn of the thyroid cartilage backward and downward, opposing in some measure the part of the Crico-thyroid muscle which is connected to the anterior margin of the horn.

FIG. 370.—Vertical section of the larynx and upper part of the trachea.

The *Crico-arytenoideus lateralis* is smaller than the preceding, and of an oblong form. It arises from the upper border of the side of the cricoid cartilage, and, passing obliquely upward and backward, is inserted into the outer angle of the base of the arytenoid cartilage in front of the preceding muscle.

FIG. 571.—Muscles of larynx. Side view. Right ala of thyroid cartilage removed.

The *Thyro-arytenoideus* is a broad, flat muscle which lies parallel with the outer side of the true vocal cord. It arises in front from the lower half of the receding angle of the thyroid cartilage and from the crico-thyroid membrane. Its fibres pass horizontally backward and outward, to be inserted into the base and anterior surface of the arytenoid cartilage. This muscle consists of two fasciculi. The *inner* or *inferior portion*, the thicker, is inserted into the anterior angle of the base of the arytenoid cartilage and into the adjacent portion of its anterior surface; it lies parallel with the true vocal cord, to which it is adherent. The *outer* or *superior fasciculus*, the thinner, is inserted into the anterior surface and outer border of the arytenoid cartilage above the preceding fibres; it lies on the outer side of the sacculus laryngis, immediately beneath the mucous membrane.¹

Arytenoideus Rectus.—This is a small but fairly constant muscle which

The *Arytenoideus* is a single muscle filling up the posterior concave surface of the arytenoid cartilages. It arises from the posterior surface and outer border of one arytenoid cartilage, and is inserted into the corresponding parts of the opposite cartilage. It consists of three planes of fibres, two oblique and one transverse. The *oblique fibres*, the most superficial, form two fasciculi, which pass from the base of one cartilage to the apex of the opposite one. The *transverse fibres*, the deepest and most numerous, pass transversely across between the two cartilages; hence the *Arytenoideus* was formerly considered as several muscles, under the name of *transversi* and *obliqui*. A few of the oblique fibres are occasionally continued round the outer margin of the cartilage, and blend with the *Thyro-arytenoid* or the *Aryteno-epiglottideus* muscle.

FIG. 572.—Interior of the larynx, seen from above. (Enlarged.)

¹ Henle describes these two portions as separate muscles, under the names of *External* and *Internal thyro-arytenoid*.

was first described by Luschka, and named by him the *Arytenoideus rectus*. It is attached below to the posterior concave surface of the arytenoid cartilage beneath the Arytenoideus muscle, and, passing upward, emerges at the upper border of this muscle, and is inserted into the posterior surface of the cartilage of Santorini.¹

The muscles of the epiglottis are the

Thyro-epiglottideus. Aryteno-epiglottideus superior.
Aryteno-epiglottideus inferior.

The *Thyro-epiglottideus* is a delicate fasciculus which arises from the inner surface of the thyroid cartilage, just external to the origin of the Thyro-arytenoid muscle, and spreads out upon the outer surface of the sacculus laryngis; some of its fibres are lost in the aryteno-epiglottidean fold, whilst others are continued forward to the margin of the epiglottis (*Depressor epiglottidis*).

The *Aryteno-epiglottideus superior* consists of a few delicate muscular fasciculi which arise from the apex of the arytenoid cartilages and become lost in the fold of mucous membrane extending between the arytenoid cartilage and side of the epiglottis (*aryteno-epiglottidean folds*).

The *Aryteno-epiglottideus inferior* (*Compressor sacculi laryngis*, Hilton) arises from the arytenoid cartilage just above the attachment of the superior vocal cord; passing forward and upward, it spreads out upon the anterior surface of the epiglottis. This muscle is separated from the preceding by an indistinct areolar interval.²

Actions.—In considering the action of the muscles of the larynx, they may be conveniently divided into two groups, viz.: 1. Those which open and close the glottis. 2. Those which regulate the degree of tension of the vocal cords.

1. The muscles which open the glottis are the *Crico-arytenoidei postici*; and those which close it are the *Arytenoideus* and the *Crico-arytenoidei laterales*. 2. The muscles which regulate the tension of the vocal cords are the *Crico-thyroidei*, which tense and elongate them; and the *Thyro-arytenoidei*, which relax and shorten them. The *Thyro-epiglottideus* is a depressor of the epiglottis, and the *Aryteno-epiglottidei* constrict the superior aperture of the larynx, compress the sacculi laryngis, and empty them of their contents.

The *Crico-arytenoidei postici* separate the chordæ vocales, and consequently open the glottis, by rotating the arytenoid cartilages outward around a vertical axis passing through the crico-arytenoid joints, so that their anterior angles and the ligaments attached to them become widely separated, the vocal cords at the same time being made tense.

The *Crico-arytenoidei laterales* close the glottis by rotating the arytenoid cartilages inward so as to approximate their anterior angles.

The *Arytenoideus* muscles approximate the arytenoid cartilages, and thus close the opening of the glottis, especially at its back part.

The *Crico-thyroid* muscles produce tension and elongation of the vocal cords. This is effected as follows: the thyroid cartilage is fixed by the Thyro-hyoid muscles; then the *Crico-thyroid* muscles, when they act, draw upward the front of the cricoid cartilage, and so depress the posterior portion, which carries with it the arytenoid cartilages, and thus elongate the vocal cords.

The *Thyro-arytenoidei* muscles, consisting of two parts having different attachments and different directions, are rather complicated as regards their action. Their main use is to draw the arytenoid cartilages forward toward the thyroid, and thus shorten and relax the vocal cords. But, owing to the connection of the inner portion with the vocal cord, this part, if acting separately, is supposed to modify its elasticity and tension, and the outer portion, being inserted into the outer part of the anterior surface of the arytenoid cartilage, may rotate it inward, and thus narrow the rima glottidis by bringing the two cords together.

The *Thyro-epiglottidei* depress the epiglottis and assist in compressing the sacculi laryngis. The *Aryteno-epiglottideus superior* constricts the superior aperture of the larynx, when it

¹ *Anatomy*, by Hyrtl, page 718.

² *MUSCULUS TRITICEO-GLOSSUS*. Bochdalek, jun. (*Prager Vierteljahrsschrift*, 2d part, 1866), describes a muscle hitherto entirely overlooked, except a brief statement in Henle's *Anatomy*, which arises from the nodule of cartilage (*corpus triticeum*) in the posterior thyro-hyoid ligament, and passes forward and upward to enter the tongue along with the *Hyo-glossus* muscle. He met with this muscle eight times in twenty-two subjects. It occurred in both sexes, sometimes on both sides, at others on one only.

is drawn upward, during deglutition, and the opening closed by the epiglottideus inferior, together with some fibres of the Thyro-arytenoid laryngis.

The **Mucous Membrane of the Larynx** is continuous at the mouth and pharynx, and is prolonged through the trachea to the lungs. It lines the posterior and upper part of the anterior cricoid cartilage to which it is closely adherent, and forms the aryteno-epiglottidean folds which encircle the superior aperture of the larynx. It lines the interior of the larynx; forms, by its reduplication, the chief part of the vocal cord; and, from the ventricle, is continued into the false vocal cord, where it is then reflected over the true vocal cords, where it is closely adherent; covers the inner surface of the crico-thyroid cartilage; and is ultimately continuous with the lining of the trachea. It is covered with columnar ciliated epithelium below, but above this point the cilia are found only in front of the epiglottis. In the rest of its extent the epithelium is of a different variety.

Glands.—The mucous membrane of the larynx is furnished with muciparous glands, the orifices of which are found in the epiglottis, being lodged in the epiglottidean folds. They are very numerous upon the epiglottis, being lodged in the epiglottidean folds. They are also found in large numbers along the posterior surface of the epiglottidean fold, in front of the arytenoid cartilages, where they are called *arytenoid glands*. They exist also in large numbers upon the saccus laryngis. None are found on the vocal cords.

Vessels and Nerves.—The *arteries of the larynx* are derived from the superior and inferior thyroid. The *veins* those accompanying the superior laryngeal artery join the internal jugular vein, which opens into the internal jugular vein; while those accompanying the inferior laryngeal artery join the inferior thyroid vein which opens into the internal jugular vein. The *lymphatics* terminate in the deep cervical glands. The *superior laryngeal* and the *inferior or recurrent laryngeal* nerves, joined by filaments from the sympathetic, supply the mucous membrane of the larynx and the trachea. The inferior laryngeal nerves supply the remaining muscles of the larynx. The muscle is supplied by both nerves.

THE TRACHEA (Fig. 573).

The **Trachea**, or **Windpipe**, is a cartilaginous and membranous tube, flattened posteriorly, which extends from the lower part of the neck, with the sixth cervical vertebra, to opposite the fourth, dorsal, where it divides into the two bronchi, one for each lung. It measures about four inches and a half in length; its diameter is from three-quarters of an inch to an inch, being always larger in the male.

Relations.—The anterior surface of the trachea is connected with the neck, from above downward, by the isthmus of the thyroid gland, the thyroid veins, the *arteria thyroidea ima* (when that vessel exists), the Sternothyroid muscles, the cervical fascia, and the anastomosing branches between the anterior jugular vein and the thyroidea ima artery. It is covered from before backward by the first piece of the sternum, the thymus gland, the left innominate vein, the arch of the aorta, the left carotid arteries, and the deep cardiac plexus. Posteriorly, it is connected with the œsophagus; laterally, in the neck, it is in relation with the common carotid arteries, the lateral lobes of the thyroid gland, the recurrent laryngeal nerves; and in the thorax it lies between the pleuræ, having the pneumogastric nerve on each side of it.

The **Right Bronchus**, wider, shorter, and more horizontal,

left, is about an inch in length, and enters the right lung opposite the fifth dorsal vertebra. The vena azygos major arches over it from behind, and the right pulmonary artery lies below and then in front of it.

The **Left Bronchus** is smaller, longer, and more oblique than the right, being nearly two inches in length. It enters the root of the left lung opposite the sixth dorsal vertebra, about an inch lower than the right bronchus. It passes beneath the arch of the aorta, crosses, in front of the œsophagus, the thoracic duct and

FIG. 573.—Front view of cartilages of larynx; the trachea and bronchi.

the descending aorta, and has the left pulmonary artery lying at first above and then in front of it. If a transverse section is made across the trachea a short distance above its point of bifurcation, and a bird's-eye view taken of its interior (Fig. 574), the septum placed at the bottom of the trachea and separating the two bronchi will be seen to occupy the left of the median line, so that any solid body dropping into the trachea would naturally be directed toward the right bronchus. This tendency is aided by the larger size of the right tube as compared with its fellow. This fact serves to explain why a foreign body in the trachea generally falls into the right bronchus.¹

¹ Reigel asserts that the entry of a foreign body into the *left* bronchus is by no means so infrequent as is generally supposed.

Structure.—The trachea is composed of imperfect cartilaginous rings, fibrous membrane, muscular fibres, longitudinal yellow elastic fibres, mucous membrane, and glands.

The cartilages vary from sixteen to twenty in number: each forms an imperfect ring which surrounds about two-thirds of the cylinder of the trachea, being imperfect behind, where the tube is completed by fibrous membrane. The cartilages are placed horizontally above each other, separated by narrow membranous intervals. They measure about two lines in depth and half a line in thickness. Their outer surfaces are flattened, but internally they are convex from being thicker in the middle than at the margins. Two or more of the cartilages often unite partially or completely, and are sometimes bifurcated at their extremities. They are highly elastic, but sometimes become calcified in advanced life. In the right bronchus the cartilages vary in number from six to eight; in the left, from nine

FIG. 571.—Transverse section of the trachea, just above its bifurcation, with a bird's-eye view of the interior.

to twelve. They are shorter and narrower than those of the trachea. The peculiar cartilages are the first and the last.

The *first cartilage* is broader than the rest, and sometimes divided at one end: it is connected by fibrous membrane with the lower border of the cricoid cartilage, with which or with the succeeding cartilage it is sometimes blended.

The *last cartilage* is thick and broad in the middle, in consequence of its lower border being prolonged into a triangular hook-shaped process which curves downward and backward between the two bronchi. It terminates on each side in an imperfect ring which encloses the commencement of the bronchi. The cartilage above the last is somewhat broader than the rest at its centre.

The Fibrous Membrane.—The cartilages are enclosed in an elastic fibrous membrane which forms a double layer, one layer, the thicker of the two, passing over the outer surface of the ring, the other over the inner surface: at the upper and lower margins of the cartilages these two layers blend together to form a single membrane which connects the rings one with another. They are thus, as it were, imbedded in the membrane. In the space behind, between the extremities of the rings, the membrane forms a single distinct layer.

The **muscular fibres** are disposed in two layers, longitudinal and transverse. The *longitudinal fibres* are the most external, and arise by minute tendons from the inner surfaces of the ends of the tracheal cartilages and from the fibrous membrane.

The *transverse fibres* (Trachealis muscle, Todd and Bowman), the most internal, form a thin layer which extends transversely between the ends of the cartilages and the intervals between them at the posterior part of the trachea. The muscular fibres are of the unstriped variety.

The **elastic fibres** form a complete lining to the entire cylinder of the trachea, external to the mucous membrane; they are most abundant at the posterior part of the tube between the extremities of the rings, where they are collected into distinct longitudinal bundles, and are especially numerous about the bifurcation of the trachea. They may be traced downward as a continuous membrane to the ultimate ramifications of the bronchial tubes. The fibres are contained in a loose submucous tissue which contains numerous mucous glands.

The **Mucous Membrane** is continuous above with that of the larynx, and below

with that of the bronchi. Microscopically, it presents a well-marked basement membrane supporting a layer of columnar ciliated epithelium, between the deeper ends of which are smaller round or elongated cells. It contains a large amount of lymphoid tissue and some tracheal glands.

The **Tracheal Glands** are found in great abundance at the posterior part of the trachea. They are small, flattened, ovoid bodies placed upon the outer surface of the fibrous layer; each is furnished with an excretory duct which pierces the fibrous and muscular layers and opens on the surface of the mucous membrane. Some glands of smaller size are also found at the sides of the trachea, between the layers of fibrous tissue connecting the rings, and others immediately beneath the mucous coat. The secretion from these glands serves to lubricate the inner surface of the trachea.

Vessels and Nerves.—The trachea is supplied with blood by the inferior thyroid arteries. The *veins* terminate in the thyroid venous plexus. The *nerves* are derived from the pneumogastric and its recurrent branches and from the sympathetic.

Surface Form.—In the middle line of the neck some of the cartilages of the larynx can be readily distinguished. In the receding angle below the chin the hyoid bone can easily be made out (see page 230), and a finger's breadth below it is the *pomum Adami*, the prominence between the upper borders of the two *alæ* of the thyroid cartilage. About an inch below this, in the middle line, is a depression corresponding to the crico-thyroid space, in which the operation of laryngotomy is performed. This depression is bounded below by a prominent arch, the anterior ring of the cricoid cartilage, below which the trachea can be felt, though it is only in the emaciated adult that the separate rings can be distinguished. The lower part of the trachea is not easily made out, for as it descends in the neck it takes a deeper position and is farther removed from the surface. The level of the vocal cords corresponds to the middle of the anterior margin of the thyroid cartilage.

With the laryngoscope the following structures can be seen: The base of the tongue and the upper surface of the epiglottis, with the glosso-epiglottic ligaments, the superior aperture of the larynx, bounded on either side by the aryteno-epiglottidean ligaments, in which may be seen two rounded eminences corresponding to the cornicula and cuneiform cartilages. Beneath these, the true and false vocal cords, with the ventricle between them. Still deeper, the cricoid cartilage and some of the anterior parts of the rings of the trachea, and sometimes, in deep inspiration, the bifurcation of the trachea.

Surgical Anatomy.—*Foreign bodies* often find their way into the air-passages. These may be either large soft substances, as a piece of meat, when they become lodged in the upper aperture of the larynx or in the rima glottidis, and cause speedy suffocation unless rapidly got rid of or unless an opening is made into the air-passages below, so as to enable the patient to breathe. Smaller bodies, and frequently of a hard nature, such as cherry- or plum-stones, small pieces of bone, buttons, etc., may find their way through the rima glottidis into the trachea or bronchus, or may become lodged in the ventricle of the larynx. The dangers then depend not so much upon the mechanical obstruction as upon the spasm of the glottis which they excite from reflex irritation. When lodged in the ventricle of the larynx they may produce very few symptoms beyond sudden loss of voice or alteration in the voice sounds immediately following the inhalation of the foreign body. When, however, they are situated in the trachea, they are constantly striking against the vocal cords during expiratory efforts, and produce attacks of dyspnoea from spasm of the glottis. When lodged in the bronchus they usually become fixed there, and, occluding the lumen of the tube, cause a loss of the respiratory murmur on the affected side, which is, as stated above, usually the right.

Beneath the mucous membrane of the upper part of the air-passages there is a considerable amount of submucous tissue which is liable to become much swollen from effusion in inflammatory affections, constituting the disease known as "oedema of the glottis." This effusion does not extend below the level of the vocal cords, on account of the fact that the mucous membrane is closely adherent to these structures, without the intervention of any submucous tissue. So that, in cases of this disease in which it is necessary to open the air-passages to prevent suffocation, the operation of laryngotomy is sufficient.

Chronic laryngitis is an inflammation of the mucous glands of the larynx which occurs in those who speak much in public, and is known as "clergyman's sore throat." It is due to the dryness induced by the large amount of cold air drawn into the air-passages during prolonged speaking, which excites the increased activity of the mucous glands to keep the parts moist, and this eventually terminates in inflammation of these structures.

Ulceration of the larynx may occur from syphilis, either superficial ulceration or from the softening of a gumma, from tubercular disease (laryngeal phthisis), or from malignant disease (epithelioma).

The air-passages may be opened in two different situations: through the crico-thyroid membrane (*laryngotomy*), or in some part of the trachea (*tracheotomy*); and to these some surgeons

have added a third method, by opening the crico-thyroid membrane and dividing the cricoid cartilage with the upper ring of the trachea (*laryngo-tracheotomy*). The student should carefully consider the relative anatomy of the air-tube in each of these situations (Fig. 575).

FIG. 575.—Surgical anatomy of laryngo-tracheal region. In the infant.

Laryngotomy is anatomically the most simple operation: it can most readily be performed, and should always be preferred when particular circumstances do not render the operation of tracheotomy absolutely necessary. The crico-thyroid membrane is very superficial, being covered only in the middle line by the skin, superficial fascia, and the deep fascia. On each side of the middle line it is also covered by the Sterno-hyoid and Sterno-thyroid muscles, which diverge slightly from each other at their upper parts, leaving a slight interval between them. On these muscles rests the anterior jugular vein. The only vessel of any importance in connection with this operation is the crico-thyroid artery, which crosses the crico-thyroid membrane, and which may be wounded, but rarely gives rise to any trouble. The operation is performed thus: The head being thrown back and steadied by an assistant, the finger is passed over the front of the neck and the crico-thyroid depression felt for. A vertical incision is then made through the skin in the middle line over this spot, and carried down through the fascia until the crico-thyroid membrane is exposed. A cross cut is then made through the membrane, close to the upper border of the cricoid cartilage, so as to avoid, if possible, the crico-thyroid artery, and a tracheotomy-tube introduced. It has been recommended, as a more rapid way of performing the operation, to make a transverse instead of a longitudinal cut through the superficial structures, and thus to open at once the air-passages. It will be seen, however, that in operating in this way the anterior jugular veins would be in danger of being wounded.

Tracheotomy may be performed either above or below the isthmus of the thyroid body, or this structure may be divided and the trachea opened beneath it.

The isthmus of the thyroid gland usually crosses the second and third rings of the trachea; along its upper border is frequently to be found a large transverse communicating branch between the superior thyroid veins; and the isthmus itself is covered by a venous plexus formed between the thyroid veins of the opposite sides. Theoretically, therefore, it is advisable to avoid dividing this structure in opening the trachea.

Above the isthmus the trachea is comparatively superficial, being covered by the skin, superficial fascia, deep fascia, Sterno-hyoid and Sterno-thyroid muscles, and a second layer of the deep fascia, which, attached above to the lower border of the hyoid bone, descends beneath the muscles to the thyroid body, where it divides into two layers and encloses the isthmus.

Below the isthmus the trachea lies much more deeply, and is covered by the Sterno-hyoid and the Sterno-thyroid muscles and a quantity of loose areolar tissue in which is a plexus of veins, some of them of large size; they converge to two trunks, the inferior thyroid veins, which descend on either side of the median line on the front of the trachea and open into the innominate veins. In the infant the thymus gland ascends a variable distance along the front of the trachea, and opposite the episternal notch the windpipe is crossed by the left innominate vein. Occasionally also, in young subjects, the innominate artery crosses the tube obliquely above the level of the sternum. The thyroidea ima artery, when that vessel exists, passes from below upward along the front of the trachea.

From these observations it must be evident that the trachea can be more readily opened above than below the isthmus of the thyroid body.

Tracheotomy above the isthmus is performed thus: The patient should, if possible, be laid on his back on a table in a good light. A pillow is to be placed under the shoulders and the head thrown back and steadied by an assistant. The surgeon, standing on the right side of his patient, makes an incision from an inch and a half to two inches in length in the median line of the neck from the top of the cricoid cartilage. The incision must be made exactly in the middle line, so as to avoid the anterior jugular veins, and after the superficial structures have been divided the interval between the Sterno-hyoid muscles must be found, the raphe divided, and the muscles drawn apart. The lower border of the cricoid cartilage must now be felt for, and the upper part of the trachea exposed from this point downward in the middle line. Bose has recommended that the layer of fascia in front of the trachea should be divided transversely at the level of the lower border of the cricoid cartilage, and, having been seized with a pair of forceps, pressed downward with the handle of the scalpel. By this means the isthmus of the thyroid gland is depressed, and is saved from all danger of being wounded, and the trachea cleanly exposed. The trachea is now transfixed with a sharp hook and drawn forward in order to steady it, and is then opened by inserting the knife into it and dividing the two or three upper rings from below upward. If the trachea is to be opened below the isthmus, the incision must be made from a little below the cricoid cartilage to the top of the sternum.

In the child the trachea is smaller, more deeply placed, and more movable than in the adult. In fat or short-necked people, or in those in whom the muscles of the neck are prominently developed, the trachea is more deeply placed than in the opposite conditions.

A portion of the larynx or the whole of it has been removed for malignant disease. The results which have been obtained from the removal of the whole of it have not been very satisfactory, and the cases in which the operation is justifiable are very few. It may be removed by a median incision through the soft parts, freeing the cartilage from the muscles and other structures in front, separating the larynx from the trachea below, and dissecting off the deeper structure from below upward.

THE PLEURÆ.

Each lung is invested, upon its external surface, by an exceedingly delicate serous membrane, the *pleura*, which encloses the organ as far as its root, and is then reflected upon the inner surface of the thorax. The portion of the serous membrane investing the surface of the lung is called the *pleura pulmonalis* (visceral layer of pleura), while that which lines the inner surface of the chest is called the *pleura costalis* (parietal layer of pleura). The space between these two layers is called the *cavity of the pleura*, but it must be borne in mind that in the healthy condition the two layers are in contact, and there is no real cavity until the lung becomes collapsed and a separation of it from the wall of the chest takes place. Each pleura is therefore a shut sac, one occupying the right, the other the left half of the thorax, and they are perfectly separate, not communicating with each other. The two pleuræ do not meet in the middle line of the chest, excepting anteriorly opposite the upper part of the second piece of the sternum—a space being left between them, which contains all the viscera of the thorax excepting the lungs: this is the *mediastinum*.

Reflections of the Pleura (Fig. 576).—Commencing at the sternum, the pleura passes outward, covers the costal cartilages, the inner surface of the ribs and Intercostal muscles, and at the back part of the thorax passes over the thoracic ganglia and their branches, and is reflected upon the sides of the bodies of the vertebræ, where it is separated by a narrow interval, the *posterior mediastinum*, from the opposite pleura. From the vertebral column the pleura passes to the side of the pericardium, which it covers to a slight extent; it then covers the back part of the root of the lung, from the lower border of which a triangular fold descends vertically by the side of the posterior mediastinum to the Diaphragm. This fold is the broad ligament of the lung, the *Ligamentum latum pulmonis*, and serves to retain the lower part of that organ in position. From the root the pleura may be traced over the convex surface of the lung, the summit and base, and also over the sides of the fissures between the lobes on to its anterior surface and the front part of its root; from this it is reflected upon the side of the pericardium to the inner surface of the sternum. Below, it covers the upper surface of the Diaphragm, and extends in front as low as the costal cartilage of the seventh rib; at the side of the chest, as low as the tenth rib on the left side and the ninth on the right side; and

behind, it reaches as low as the twelfth rib, and sometimes even beyond it, as low as the transverse process of the first lumbar vertebra. Above, its apex projects, in the form of a *cul-de-sac*, through the superior opening of the thorax into the neck, extending from one to two inches above the margin of the first rib, and receives the summit of the corresponding lung; this sac is strengthened, according to Dr. Sibson, by a dome-like expansion of fascia, attached in front to the posterior border of the first rib, and behind to the anterior border of the transverse process of the

FIG. 376.—A transverse section of the thorax, showing the relative position of the viscera and the reflections of the pleura.

seventh cervical vertebra. This is covered and strengthened by a few spreading muscular fibres derived from the *Scaleni* muscles.

A little above the middle of the sternum, the contiguous surfaces of the two pleurae are sometimes in contact for a slight extent; but above and below this point the interval left between them forms part of the mediastinum.

The inner surface of the pleura is smooth, polished, and moistened by a serous fluid; its outer surface is intimately adherent to the surface of the lung and to the pulmonary vessels as they emerge from the pericardium; it is also adherent to the upper surface of the Diaphragm; throughout the rest of its extent it is somewhat thicker, and may be separated from the adjacent parts with extreme facility.

The right pleural sac is shorter, wider, and reaches higher in the neck than the left.

Vessels and Nerves.—The arteries of the pleura are derived from the intercostal, the internal mammary, the musculo-phrenic, thymic, pericardiac, and bronchial. The veins correspond to the arteries. The lymphatics are very numerous. The nerves are derived from the phrenic and sympathetic (Luschka). Kölliker states that nerves accompany the ramification of the bronchial arteries in the pleura pulmonalis.

Surgical Anatomy.—In operations upon the kidney it must be borne in mind that the pleura may sometimes extend below the level of the last rib, and may therefore be opened in these operations, especially when the last rib is removed in order to give more room.

THE MEDIASTINUM.

The **Mediastinum** is the space left in the median line of the chest by the non-approximation of the two pleuræ. It extends from the sternum in front to the spine behind, and contains all the viscera in the thorax excepting the lungs. The mediastinum may be divided for purposes of description into two parts—an

FIG. 577.—The posterior mediastinum.

upper portion, above the upper level of the pericardium, which is named the *Superior mediastinum* (Struthers); and a lower portion, below the upper level of the pericardium. This lower portion is again subdivided into three—that part which contains the pericardium and its contents, the *middle mediastinum*; that part which is in front of the pericardium, the *anterior mediastinum*; and that part which is behind the pericardium, the *posterior mediastinum*.

The **superior mediastinum** is that portion of the interpleural space which lies above the upper level of the pericardium, between the manubrium sterni in front and the upper dorsal vertebrae behind. It is bounded below by a plane passing backward from the junction of the manubrium and gladiolus sterni to the lower part of the body of the fourth dorsal vertebra. It contains the origins of the Sternohyoid and Sterno-thyroid muscles and the lower ends of the Longi colli muscles; the transverse portion of the arch of the aorta; the innominate, the thoracic portion of the left carotid and subclavian arteries; the upper half of the superior vena cava and the innominate veins, and the left superior intercostal vein; the pneumogastric, cardiac, phrenic, and left recurrent laryngeal nerves; the trachea, oesophagus, and thoracic duct; the remains of the thymus gland and lymphatics.

The **anterior mediastinum** is bounded in front by the sternum, on each side by the pleura, and behind by the pericardium. Owing to the oblique position of the

FIG. 578.—Transverse section through the upper margin of the third dorsal vertebra. (Braune.)

heart toward the left side, this space is not parallel with the sternum, but directed obliquely from above downward and to the left of the median line; it is broad below, narrow above, very narrow opposite the first segment of the gladiolus of the sternum, the contiguous surfaces of the two pleuræ being occasionally united over a small space. The anterior mediastinum contains the origins of the Triangularis sterni muscles, and a quantity of loose areolar tissue in which some lymphatic vessels are found ascending from the convex surface of the liver, and two or three lymphatic glands (anterior mediastinal glands).

The **middle mediastinum** is the broadest part of the interpleural space. It contains the heart enclosed in the pericardium, the ascending aorta, the lower half of the superior vena cava, with the vena azygos major opening into it, the bifurcation of the trachea and the two bronchi, the pulmonary artery dividing into its two branches and the right and left pulmonary veins, the phrenic nerves, and some bronchial lymphatic glands.

The **posterior mediastinum** is an irregular triangular space running parallel with the vertebral column; it is bounded in front by the pericardium and roots of

the lungs, behind by the vertebral column from the lower border of the fourth dorsal vertebra, and on either side by the pleura. It contains the descending thoracic aorta, the greater and lesser azygos veins, the pneumogastric and splanchnic nerves, the œsophagus, thoracic duct, and some lymphatic glands.

THE LUNGS.

The **Lungs** are the essential organs of respiration; they are two in number, placed one on each side of the chest, separated from each other by the heart and other contents of the mediastinum. Each lung is conical in shape, and presents for examination an apex, a base, two borders, and two surfaces (Fig. 579).

FIG. 579.—Front view of the heart and lungs.

The *apex* forms a tapering cone which extends into the root of the neck about an inch to an inch and a half above the level of the first rib.

The *base* is broad, concave, and rests upon the convex surface of the Diaphragm; its circumference is thin, and fits into the space between the lower ribs and the costal attachment of the Diaphragm, extending lower down externally and behind than in front.

The *external* or *thoracic surface* is smooth, convex, of considerable extent, and corresponds to the form of the cavity of the chest, being deeper behind than in front.

The *inner surface* is concave. It presents in front a depression corresponding to the convex surface of the pericardium, and behind a deep fissure (the hilum pulmonis) which gives attachment to the root of the lung.

The *posterior border* is rounded and broad, and is received into the deep concavity on either side of the spinal column. It is much longer than the anterior border, and projects below between the ribs and the Diaphragm.

The *anterior border* is thin and sharp, and overlaps the front of the pericardium.

Each lung is divided into two lobes, an upper and lower, by a long and deep fissure which extends from the upper part of the posterior border of the organ, about three inches from its apex, downward and forward to the lower part of its anterior border. This fissure penetrates nearly to the root. In the right lung the upper lobe is partially subdivided by a second and shorter fissure which extends from the middle of the preceding, forward and upward, to the anterior margin of the organ, marking off a small triangular portion, the middle lobe.

The *right lung* is the larger and heavier; it is broader than the left, owing to the inclination of the heart to the left side; it is also shorter by an inch, in consequence of the Diaphragm rising higher on the right side to accommodate the liver.

The Root of the Lungs.—A little above the middle of the inner surface of each lung, and nearer its posterior than its anterior border, is its root, by which the lung is connected to the heart and the trachea. The root is formed by the bronchial tube, the pulmonary artery, the pulmonary veins, the bronchial arteries and veins, the pulmonary plexus of nerves, lymphatics, bronchial glands, and areolar tissue, all of which are enclosed by a reflection of the pleura. The root of the right lung lies behind the superior vena cava and ascending portion of the aorta and below the vena azygos major. That of the left lung passes beneath the arch of the aorta and in front of the descending aorta; the phrenic nerve and the anterior pulmonary plexus lie in front of each, and the pneumogastric and posterior pulmonary plexus behind each.

The chief structures composing the root of each lung are arranged in a similar manner from before backward on both sides—viz. the pulmonary veins most anterior; the pulmonary artery in the middle; and the bronchus, together with the bronchial vessels, behind. From above downward, on the two sides, their arrangement differs, thus:

On the right side their position is—bronchus, pulmonary artery, pulmonary veins; but on the left side their position is—pulmonary artery, bronchus, pulmonary veins; this is accounted for by the bronchus being placed on a lower level on the left than on the right side, in order that it may pass under the arch of the aorta.

The *weight* of both lungs together is about forty-two ounces, the right lung being two ounces heavier than the left; but much variation is met with according to the amount of blood or serous fluid they may contain. The lungs are heavier in the male than in the female, their proportion to the body being in the former as 1 to 37, in the latter as 1 to 43. The specific gravity of the lung-tissue varies from 0.345 to 0.746, water being 1000.

The *color* of the lungs at birth is a pinkish-white; in adult life a dark slate-color, mottled in patches; and as age advances this mottling assumes a black color. The coloring matter consists of granules of a carbonaceous substance deposited in the areolar tissue near the surface of the organ. It increases in quantity as age advances, and is more abundant in males than in females. The posterior border of the lung is usually darker than the anterior.

The *surface* of the lung is smooth, shining, and marked out into numerous polyhedral spaces, indicating the lobules of the organ; the area of each of these spaces is crossed by numerous lighter lines.

The *substance* of the lung is of a light, porous, spongy texture; it floats in water and crepitates when handled, owing to the presence of air in the tissue; it is also highly elastic; hence the collapsed state of these organs when they are removed from the closed cavity of the thorax.

Structure.—The lungs are composed of an external serous coat, a subserous areolar tissue, and the pulmonary substance or parenchyma.

The *serous coat* is derived from the pleura; it is thin, transparent, and invests the entire organ as far as the root.

The *subserous areolar tissue* contains a large proportion of elastic fibres;

it invests the entire surface of the lung, and extends inward between the lobules.

The *parenchyma* is composed of lobules which, although closely connected together by an interlobular areolar tissue, are quite distinct from one another, and may be teased asunder without much difficulty in the *fœtus*. The lobules vary in size: those on the surface are large, of pyramidal form, the base turned toward the surface; those in the interior smaller and of various forms. Each lobule is composed of one of the ramifications of a bronchial tube and its terminal air-cells, and of the ramifications of the pulmonary and bronchial vessels, lymphatics, and nerves, all of these structures being connected together by areolar tissue.

The *bronchus*, upon entering the substance of the lung, divides and subdivides dichotomously throughout the entire organ. Sometimes three branches arise together, and occasionally small lateral branches are given off from the sides of a main trunk. Each of the smaller subdivisions of the bronchi enters a pulmonary lobule, and is termed a *lobular bronchial tube*. Its wall now begins to present irregular dilatations, at first sparingly and on one side of the tube only, but as it proceeds onward these dilatations become more numerous and surround the tube on all sides, so that it loses its cylindrical character, and, becoming enlarged, terminates in a sacculated alveolar passage beset in all directions, both laterally and terminally, by caecal pouches or *air-cells*. The enlarged terminations—that is, the alveolar passages from which the caecal pouches or air-cells spring—are termed *infundibula*. Within the lungs the bronchial tubes are circular, not flattened, and present certain peculiarities of structure.

Changes in the Structure of the Bronchi in the Lungs.—1. *In the Lobes of the Lungs.*—In the lobes of the lungs the following changes take place: The *cartilages* are not imperfect rings, but consist of thin laminae, of varied form and size, scattered irregularly along the sides of the tube, being most distinct at the points of division of the bronchi. They may be traced into tubes the diameter of which is only one-fourth of a line. Beyond this point the tubes are wholly membranous. The fibrous coat and the longitudinal elastic fibres are continued into the smallest ramifications of the bronchi. The muscular coat is disposed in the form of a continuous layer of annular fibres, which may be traced upon the smallest bronchial tubes, and consists of the unstriped variety of muscular tissue. The mucous membrane lines the bronchi and its ramifications throughout, and is covered with columnar ciliated epithelium.

2. *In the Lobules of the Lung.*—In the lobular bronchial tubes and in the infundibula the following changes take place: The muscular tissue begins to disappear, so that in the infundibula there is scarcely a trace of it. The longitudinal elastic fibres begin to break up, so that in the infundibula they form an interlacement around the mouths of the air-cells which spring from it. The epithelium becomes non-ciliated and flattened. This occurs gradually; thus, in the lobular bronchial tubes patches of non-ciliated flattened epithelium may be found scattered amongst the columnar ciliated epithelium; then these patches of non-ciliated flattened epithelium become more and more numerous, until in the infundibula and air-cells all the epithelium is of the non-ciliated pavement variety. In addition to these flattened cells, there are small polygonal granular cells in the air-sacs, in clusters of two or three, between the others.

The air-cells are small, polyhedral, alveolar recesses composed of a fibrillated connective tissue and surrounded by a few involuntary muscular and elastic fibres. In their walls are granular, rounded, amœboid cells often containing carbonaceous particles. The air-cells are well seen on the surface of the lung, and vary from $\frac{1}{100}$ th to $\frac{1}{6}$ th of an inch in diameter, being largest on the surface at the thin borders and at the apex, and smallest in the interior.

The *pulmonary artery* conveys the venous blood to the lungs; it divides into branches which accompany the bronchial tubes, and terminates in a dense capillary

network upon the walls of the intercellular passages and air-cells. In the lung the branches of the pulmonary artery are usually above and in front of a bronchial tube, the vein below.

The *pulmonary capillaries* form plexuses which lie immediately beneath the mucous membrane in the walls and septa of the air-cells and of the infundibula. In the septa between the air-cells the capillary network forms a single layer. The capillaries form a very minute network, the meshes of which are smaller than the vessels themselves;¹ their walls are also exceedingly thin. The vessels of neighboring lobules are distinct from each other, and do not anastomose; and, according to Dr. Waters,² those of the separate groups of infundibula with their air-cells (which groups he denominates lobulettes) are also independent, so that in the septa between two adjoining lobulettes there would be a double layer of capillaries, one layer belonging to each of the adjacent infundibula with their air-cells. If this is really the arrangement of the vessels, it would follow that, in the septa between the air-cells, the blood in the capillaries would be exposed on all sides to the action of the air, since it is circulating in a single layer of vessels which is in contact with the membrane of the air-cells on both sides; but that, in the septa between the neighboring infundibula, with their air-cells, the blood being in a double layer of capillaries, it will be in contact with the air on one side only.

The *pulmonary veins* commence in the pulmonary capillaries, the radicles coalescing into larger branches, which accompany the arteries and return the oxygenated blood to the left auricle of the heart.

The *bronchial arteries* supply blood for the nutrition of the lung: they are derived from the thoracic aorta, and, accompanying the bronchial tubes, are distributed to the bronchial glands and upon the walls of the larger bronchial tubes and pulmonary vessels. Those supplying the bronchial tubes form a capillary plexus in the muscular coat, from which branches are given off to form a second plexus in the mucous coat. This plexus communicates with branches of the pulmonary artery and empties itself into the pulmonary vein. Others are distributed in the interlobular areolar tissue, and terminate partly in the deep, partly in the superficial, bronchial veins. Lastly, some ramify upon the surface of the lung beneath the pleura, where they form a capillary network.

The *bronchial vein* is formed at the root of the lung, receiving superficial and deep veins corresponding to branches of the bronchial artery. It does not, however, receive all the blood supplied by the artery, as some of it passes into the pulmonary vein. It terminates on the right side in the vena azygos major, and on the left side in the superior intercostal vein.

The *lymphatics* consist of a superficial and deep set: they terminate at the root of the lung, in the bronchial glands.

Nerves.—The lungs are supplied from the anterior and posterior pulmonary plexuses, formed chiefly by branches from the sympathetic and pneumogastric. The filaments from these plexuses accompany the bronchial tubes, upon which they are lost. Small ganglia are found upon these nerves.

Surface Form.—The apex of the lung is situated in the neck, behind the interval between the two heads of origin of the Sterno-mastoid. The height to which it rises above the clavicle varies very considerably, but is generally about one inch. It may, however, extend as much as an inch and a half or an inch and three-quarters, or, on the other hand, it may scarcely project above the level of this bone. In order to mark out the anterior margin of the lung, a line is to be drawn from the apex-point, one inch above the level of the clavicle, and rather nearer the posterior than the anterior border of the Sterno-mastoid muscle, downward and inward across the sterno-clavicular articulation and first piece of the sternum until it meets, or almost meets, its fellow of the other side opposite the articulation of the manubrium and gladiolus. From this point the two lines are to be drawn downward, one on either side of the mesial line and close to

¹ The meshes are only 0.002''' to 0.008''' in width, while the vessels are 0.003''' to 0.005''' (Kölliker, *Human Microscopic Anatomy*).

² *Med.-Chir. Trans.*, vol. xxviii., 1845.

FIG. 380.—The roots of the lungs and posterior pulmonary plexus, seen from behind.

it, as far as the level of the articulation of the fourth costal cartilages to the sternum. From here the two lines diverge: the left is to be drawn at first passing outward with a slight inclination downward, and then taking a bend downward with a slight inclination outward to the apex of the heart, and thence to the sixth costo-chondral articulation. The direction of the anterior border of this part of the left lung is denoted with sufficient accuracy by a curved line with its convexity directed upward and outward from the articulation of the fourth right costal cartilage of the sternum to the fifth intercostal space, an inch and a half below and three-quarters of an inch internal to the left nipple. The continuation of the anterior border of the right lung is marked by a prolongation of its line from the level of the fourth costal cartilages vertically downward as far as the sixth, when it slopes off along the line of the sixth costal cartilage to its articulation with the rib.

The lower border of the lung is marked out by a slightly curved line with its convexity downward from the articulation of the sixth costal cartilage to its rib to the spinous process of the tenth dorsal vertebra. If vertical lines are drawn downward from the nipple, the mid-axillary line, and the apex of the scapula, while the arms are raised from the sides, they should intersect this convex line, the first at the sixth, the second at the eighth, and the third at the tenth rib. It will thus be seen that the pleura (see page 997) extends farther down than the lung, so that it may be wounded, and a wound pass through its cavity into the Diaphragm, and even injure the abdominal viscera, without the lung being involved.

The posterior border of the lung is indicated by a line drawn from the level of the spinous process of the seventh cervical vertebra, down either side of the spine, corresponding to the costo-vertebral joints as low as the spinous process of the tenth dorsal vertebra. The trachea bifurcates opposite the spinous process of the fourth dorsal vertebra, and from this point the two bronchi are directed outward, the right one almost horizontally, the left with a considerable inclination downward.

The position of the great fissure in the right lung may be indicated by a line drawn from the fourth dorsal vertebra round the side of the chest to the anterior margin of the lung opposite the seventh rib, and the smaller or secondary fissure by a line drawn from the preceding where it bisects the mid-axillary line to the junction of the fourth costal cartilage to the sternum. The great fissure in the left lung is a little higher, extending from the third dorsal vertebra round the side of the chest to reach the anterior margin of the lung opposite the sixth costal cartilage.

Surgical Anatomy.—The lungs may be wounded or torn in three ways: (1) By compression of the chest, without any injury to the ribs. (2) By a fractured rib penetrating the lung. (3) By stabs, gunshot wounds, etc.

The first form, where the lung is ruptured by external compression without any fracture of the ribs, is very rare, and usually occurs in young children, and affects the root of the lung—the most fixed part—and thus, implicating the great vessels, is frequently fatal. It would seem *a priori* a most unusual injury, and its exact mode of causation is difficult to interpret. The probable explanation is that immediately before the compression is applied a deep inspiration is taken and the lungs are fully inflated; owing then to spasm of the glottis at the moment of compression, the air is unable to escape from the lung, which is not able to recede, and consequently gives way.

In the second variety, when the wound in the lung is produced by the penetration of a broken rib, both the pleura costalis and pulmonalis must necessarily be injured, and consequently the air taken into the wounded air-cells may find its way through these wounds into the cellular tissue of the parietes of the chest. This it may do without collecting in the pleural cavity; the two layers of the pleura are so intimately in contact that the air passes straight through from the wounded lung into the subcutaneous tissue. Emphysema constitutes therefore the most important sign of injury to the lung in cases of fracture of the ribs. Pneumothorax, or air in the pleural cavity, is much more likely to occur in injuries to the lung of the third variety; that is to say, from external wounds, from stabs, gunshot injuries, and such like, in which cases air passes either from the wound of the lung or from the external wound into the cavity of the pleura during the respiratory movements. In these cases there is generally no emphysema of the subcutaneous tissue unless the external wound is small and valvular, so that the air is drawn into the wound during inspiration, and then forced into the cellular tissue around during expiration because it cannot escape from the external wound. Occasionally in wounds of the parietes of the chest no air finds its way into the cavity of the pleura, because the lung at the time of the accident protrudes through the wound and blocks the opening. This occurs where the wound is large, and constitutes one form of *hernia* of the lung. Another form of hernia of the lung occurs, though very rarely, after wounds of the chest-wall, when the wound has healed and the cicatrix subsequently yields from the pressure of the viscera behind. It forms a globular, elastic, crepitating swelling, which enlarges during expiratory efforts, falls in during inspiration, and disappears on holding the breath.

THE THYROID GLAND.

The thyroid gland bears much resemblance in structure to other glandular organs, and was formerly classified, together with the thymus, suprarenal capsules, and spleen, under the head of *ductless glands*, since when fully developed it has no excretory duct. From its situation in connection with the trachea and larynx,

the thyroid body is usually described with those organs, although it takes no part in the function of respiration. It is situated at the upper part of the trachea, and consists of two lateral lobes placed one on each side of that tube and connected together by a narrow transverse portion, the *isthmus*.

Its *anterior surface* is convex, and covered by the Sterno-hyoid, Sterno-thyroid, and Omo-hyoid muscles.

Its *lateral surfaces*, also convex, lie in contact with the sheath of the common carotid artery.

Its *posterior surface* is concave, and embraces the trachea and larynx. The posterior borders of the gland extend as far back as the lower part of the pharynx, and on the left side to the œsophagus.

The thyroid varies in weight from one to two ounces. It is larger in females than in males, and becomes slightly increased in size during menstruation. Each lobe is somewhat conical in shape, about two inches in length, and three-quarters of an inch to an inch and a quarter in breadth, the right lobe being the larger of the two.

The *isthmus* connects the lower third of the two lateral lobes; it measures about half an inch in breadth and the same in depth, and usually covers the second and third rings of the trachea. Its situation presents, however, many variations—a point of importance in the operation of tracheotomy. Sometimes the isthmus is altogether wanting.

A third lobe, of conical shape, called the *pyramid*, occasionally arises from the upper part of the isthmus or from the adjacent portion of either lobe, but most commonly the left, and ascends as high as the hyoid bone. It is occasionally quite detached, or divided into two parts, or altogether wanting.

A few muscular bands are occasionally found attached above to the body of the hyoid bone, and below to the isthmus of the gland or its pyramidal process. These form a muscle which was named by Sömmerring the *Levator glandulæ thyroideæ*.

Structure.—The thyroid body is invested by a thin capsule of connective tissue which projects into its substance and imperfectly divides it into masses of irregular form and size. When the organ is cut into, it is of a brownish-red color, and is seen to be made up of a number of closed vesicles containing a yellow glairy fluid and separated from each other by intermediate connective tissue.

According to Dr. Baber, who has recently published some important observations on the minute structure of the thyroid,¹ the vesicles of the thyroid of the adult animal are generally closed cavities; but in some young animals (*e. g.* young dogs) the vesicles are more or less tubular and branched. This appearance he supposes to be due to the mode of growth of the gland, and merely indicating that an increase in the number of vesicles is taking place. Each vesicle is lined by a single layer of epithelium, the cells of which, though differing somewhat in shape in different animals, have always a tendency to assume a columnar form. Between the epithelial cells exists a delicate reticulum. The vesicles are of various sizes and shapes, and contain as a normal product a viscid, homogeneous, semi-fluid, slightly yellowish material which frequently contains blood, the red corpuscles of which are found in it in various stages of disintegration and decolorization, the yellow tinge being probably due to the hæmoglobin, which is thus set free from the colored corpuscles. Baber has also described in the thyroid gland of the

FIG. 581.—Two lobules from the thyroid of an infant. *a.* Small glandular vesicles with their cells. *b.* The same with incipient colloid metamorphosis, more strongly marked at *c.* *d.* Coarse lymph-canals. *e.* Fine radicles of the same. *f.* An efferent vessel of considerable size.

¹ "Researches on the Minute Structure of the Thyroid Gland," *Phil. Trans.*, part iii., 1881.

dog large round cells ("parenchymatous cells"), each provided with a single oval-shaped nucleus, which migrate into the interior of the gland-vesicles.

The capillary blood-vessels form a dense plexus in the connective tissue around the vesicles, between the epithelium of the vesicles and the endothelium of the lymph-spaces, which latter surround a greater or smaller part of the circumference of the vesicle. These lymph-spaces empty themselves into lymphatic vessels which run in the interlobular connective tissue, not uncommonly surrounding the arteries which they accompany, and communicate with a network in the capsule of the gland. Baber has found in the lymphatics of the thyroid a viscid material which is morphologically identical with the normal constituent of the vesicle.

Vessels and Nerves.—The arteries supplying the thyroid are the superior and inferior thyroid, and sometimes an additional branch (thyroidea media or ima)

FIG. 562.—Minute structure of thyroid. From a transverse section of the thyroid of a dog. (Semi-diagrammatic.) (Baber.)

from the innominate artery or the arch of the aorta, which ascends upon the front of the trachea. The arteries are remarkable for their large size and frequent anastomoses. The veins form a plexus on the surface of the gland and on the front of the trachea, from which arise the superior, middle, and inferior thyroid veins, the two former terminating in the internal jugular, the latter in the innominate vein. The lymphatics are numerous, of large size, and terminate in the thoracic and right lymphatic ducts. The nerves are derived from the middle and inferior cervical ganglia of the sympathetic.

Surgical Anatomy.—The thyroid gland is subject to enlargement, which is called goitre. This may be due to hypertrophy of any of the constituents of the gland. The simplest (parenchymatous goitre) is due to an enlargement of the follicles. The fibroid is due to increase of the interstitial connective tissue. The cystic is that form in which one or more large cysts are formed from dilatation and possibly coalescence of adjacent follicles. The pulsating goitre is where the vascular changes predominate over the parenchymatous, and the vessels of the gland are especially enlarged. Finally, there is *exophthalmic goitre* (Graves's disease), where there is great vascularity and often pulsation, accompanied by exophthalmos, palpitation, and rapid pulse.

For the relief of these growths various operations have been resorted to, such as injection of tincture of iodine or perchloride of iron, especially applicable to the cystic form of the disease, ligature of the thyroid arteries, excision of the isthmus, and extirpation of the whole or a part of the gland. This latter operation is one of difficulty, and when the entire gland has been removed the operation has been followed by a condition resembling myxœdema. In removing the organ great care must be taken to avoid tearing the capsule, as if this happens the gland-tissue bleeds profusely. The thyroid arteries should be ligatured before an attempt is made to remove the mass, and in ligaturing the inferior thyroids the position of the recurrent laryngeal nerve must be borne in mind, so as not to include it in the ligature.

THE THYMUS GLAND.

The **thymus gland** presents much resemblance in structure to other glandular organs, and is another of the organs which used formerly to be denominated *ductless glands*.

The thymus gland is a temporary organ, attaining its full size at the end of the second year, when it ceases to grow, and gradually dwindles, until at puberty it has almost disappeared. If examined when its growth is most active, it will be found to consist of two lateral lobes placed in close contact along the middle line, situated partly in the superior mediastinum, partly in the neck, and extending from the fourth costal cartilage upward as high as the lower border of the thyroid gland. It is covered by the sternum and by the origins of the Sterno-hyoid and Sterno-thyroid muscles. Below, it rests upon the pericardium, being separated from the arch of the aorta and great vessels by a layer of fascia. In the neck it lies on the front and sides of the trachea, behind the Sterno-hyoid and Sterno-thyroid muscles. The two lobes generally differ in size; they are

FIG. 583.—1. Upper portion of the thymus of a fetal pig of 2" in length, showing the bud-like lobuli and glandular elements. 2. Cells of the thymus, mostly from a man. *a*. Free nucleolus. *b*. Small cells. *c*. Larger. *d*. Larger, with oil-globules, from the ox. *e*, *f*. Cells completely filled with fat, at *f* without a nucleus. *g*, *h*. Concentric bodies. *p*. occasionally united so as to form a single mass, and sometimes separated by an intermediate lobe. The thymus is of a pinkish-gray color, soft, and lobulated on its surfaces. It is about two inches in length, one and a half in breadth below, and about three or four lines in thickness. At birth it weighs about half an ounce.

Structure.—Each lateral lobe is composed of numerous lobules held together by delicate areolar tissue, the entire gland being enclosed in an investing capsule of a similar but denser structure. The primary lobules vary in size from a pin's head to a small pea, and are made up of a number of small nodules or follicles which are irregular in shape and are more or less fused together, especially toward the interior of the gland. According to Watney, each follicle consists of a medullary and cortical portion, which differ in many essential particulars from each other. The *cortical portion* is mainly composed of lymphoid cells supported by a delicate reticulum. In addition to this reticulum, of which traces only are found in the medullary portion, there is also a network of finely-branched cells which is continuous with a similar network in the medullary portion. This network forms an adventitia to the blood-vessels. In the *medullary portion* there are but few lymphoid cells, but there are, especially toward the centre, granular cells and concentric corpuscles. The granular cells are rounded or flask-shaped masses attached (often by fibrillated extremities) to blood-vessels and to newly-formed connective tissue. The concentric corpuscles are composed of a central

mass consisting of one or more granular cells, and of a capsule which is formed of epithelioid cells which are continuous with the branched cells forming the network mentioned above.

Each follicle is surrounded by a capillary plexus from which vessels pass into the interior and radiate from the periphery toward the centre, and form a second zone just within the margin of the medullary portion. In the centre of the medulla there are very few vessels, and they are of minute size.

Dr. Watney has recently made the important observation that hæmoglobin is found in the thymus either in cysts or in cells situated near to or forming part

FIG. 584.—Minute structure of the thymus gland. Follicle of injected thymus from calf, four days old, slightly diagrammatic, magnified about 50 diameters. The large vessels are disposed in two rings, one of which surrounds the follicle, the other lies just within the margin of the medulla. (Watney.) A and B. From thymus of camel, examined without addition of any reagent. Magnified about 400 diameters. A. Large colorless cell containing small oval masses of hæmoglobin. Similar cells are found in the lymph-glands, spleen, and medulla of bone. B. Colored blood-corpuscles.

of the concentric corpuscles. This hæmoglobin varies from granules to masses exactly resembling colored blood-corpuscles, oval in the bird, reptile, and fish; circular in all mammals except in the camel. Dr. Watney has also discovered in the lymph issuing from the thymus similar cells to those found in the gland, and, like them, containing hæmoglobin either in the form of granules or masses. From these facts he arrives at the physiological conclusion that the thymus is one source of the colored blood-corpuscles.

Vessels and Nerves.—The *arteries* supplying the thymus are derived from the internal mammary and from the superior and inferior thyroid. The *veins* terminate in the left innominate vein and in the thyroid veins. The *lymphatics* are of large size, arise in the substance of the gland, and are said to terminate in the internal jugular vein. The *nerves* are exceedingly minute; they are derived from the pneumogastric and sympathetic. Branches from the descendens hypoglossi and phrenic reach the investing capsule, but do not penetrate into the substance of the gland.

THE URINARY ORGANS.

THE KIDNEYS.

THE Kidneys, two in number, are situated in the back part of the abdomen, and are for the purpose of separating from the blood certain materials which, when dissolved in a quantity of water, also separated from the blood by the kidneys, constitute the urine.

They are placed in the loins, one on each side of the vertebral column, behind the peritoneum, and surrounded by a mass of fat and loose areolar tissue. Their upper extremity is on a level with the upper border of the twelfth dorsal vertebra, their lower extremity on a level with the third lumbar. The right kidney is usually on a slightly lower level than the left, probably on account of the vicinity of the liver.

The kidneys rest on the lower part of the Diaphragm and the fascia covering the Quadratus lumborum and the Psoas magnus muscles. The right one is covered in front by the right lobe of the liver, the descending portion of the duodenum, and the ascending colon; the left one has in front the fundus of the stomach, the tail of the pancreas, and the descending colon.

Each kidney is about four inches in length, two to two and a half in breadth, and rather more than one inch in thickness. The left is somewhat longer, though narrower, than the right. The weight of the kidney in the adult male varies from $4\frac{1}{2}$ ounces to 6 ounces, in the adult female from 4 ounces to $5\frac{1}{2}$ ounces. The combined weight of the two kidneys in proportion to the body is about 1 in 240.

The kidney has a characteristic form. It is flattened on its sides, and presents at one part of its circumference a hollow. It is larger at its upper than its lower extremity. It presents for examination two surfaces, two borders, and an upper and lower extremity.

Its *anterior surface* is convex, looks forward and outward, and is partially covered by peritoneum. The upper part of this surface on the right side is in contact with the under surface of the right lobe of the liver, on which it produces a slight concave impression, the *impressio renalis* (page 952); below this the descending portion of the duodenum and the upper part of the ascending colon are connected to this surface by a quantity of loose areolar tissue. On the left side the upper part of the anterior surface of the kidney is in contact with the under surface of the stomach, and below this with the left extremity of the pancreas, whilst the lower part is connected to the descending colon by loose areolar tissue.

The *posterior surface* is flatter than the anterior, and is imbedded in areolar tissue which separates it from the Diaphragm covering the twelfth rib and from the anterior lamellæ of the lumbar fascia covering the Quadratus lumborum muscle, and internally from the fascia covering the Psoas magnus muscle.

The *external border* is convex, and is directed outward and backward toward the postero-lateral wall of the abdomen. On the left side it is in contact, at its upper part, with the spleen.

The *internal border* is concave, and is directed forward and a little downward. It presents a deep longitudinal fissure bounded by a prominent overhanging anterior and posterior lip. This fissure is named the *hilum*, and allows of the passage of the vessels, nerves, and ureter into and out of the kidney.

The *superior extremity*, directed slightly inward as well as upward, is thick

and rounded, and is surmounted by the suprarenal capsule, which covers also a small portion of the anterior surface.

The *inferior extremity*, directed a little outward as well as downward, is smaller and thinner than the superior. It extends to within two inches of the crest of the ilium.

At the hilum of the kidney the relative position of the main structures passing into and out of the kidney is as follows: the vein is in front, the artery in the middle, and the duct or ureter behind and toward the lower part. By a knowledge of these relations the student may distinguish between the right and left kidney. The kidney is to be laid on the table before the student on its posterior surface, with its lower extremity toward the observer—that is to say, with the ureter *behind* and *below* the other vessels; the hilum will then be directed to the side to which the kidney belongs.

General Structure of the Kidney.—The kidney is surrounded by a distinct investment of fibrous tissue which forms a firm, smooth covering to the organ. It closely invests it, but can be easily stripped off, in doing which, however, numerous fine processes of connective tissue and small blood-vessels are torn through. Beneath this coat a thin wide-meshed network of unstriated muscular fibre forms an incomplete covering to the organ. When the fibrous coat is stripped off, the surface of the kidney is found to be smooth and even and of a deep-red color.

In infants fissures extending for some depth may be seen on the surface of the organ, a remnant of the lobular construction of the gland. The kidney is dense

in texture, but is easily lacerable by mechanical force. In order to obtain a knowledge of the structure of the gland, a vertical section must be made from its convex to its concave border, and the loose tissue and fat removed from around the vessels and the excretory duct (Fig. 585). It will be then seen that the kidney consists of a central cavity surrounded at all parts but one by the proper kidney-substance. This central cavity is called the *sinus*, and is lined by a prolongation of the fibrous coat of the kidney, which enters through a longitudinal fissure, the *hilum* (before mentioned), which is situated at that part of the cavity which is not surrounded by kidney-structure. Through this fissure the blood-vessels of the kidney and its excretory duct pass, and therefore these structures, upon entering the kidney, are contained within the sinus. The excretory duct, or *ureter*, after entering, dilates into a wide, funnel-shaped sac named the *pelvis*. This divides into two or three tubular divisions, which subdivide into several short, truncated branches named *calices* or *infundibula*, all of which are contained in the central cavity of the kidney. The blood-vessels of the kidney, after passing through the hilum,

FIG. 585.—Vertical section of kidney.

are contained in the sinus or central cavity, lying between its lining membrane and the excretory apparatus, before entering the kidney-substance.

This central cavity, as before mentioned, is surrounded on all sides except at the hilum by the substance of the kidney, which is at once seen to consist of two parts—viz. of an external granular investing part, which is called the *cortical portion*; and of an internal part, the *medullary portion*, made up of a number of dark-colored pyramidal masses, with their bases resting on the cortical part and their apices converging toward the centre, where they form prominent papillæ which project into the interior of the calices.

The cortical substance is of a bright reddish-brown color, soft, granular, and easily lacerable. It is found everywhere immediately beneath the capsule, and is seen to extend in an arched form over the base of each medullary pyramid. The part separating the sides of any two pyramids through which the arteries and nerves enter, and the veins and lymphatics emerge, from the kidney, is called a *cortical column* or *column of Bertini* (A, A' Fig. 585); whilst that portion which stretches from one cortical column to the next, and intervenes between the base of the pyramid and the capsule (which is marked by the dotted line extending from A to A' in Fig. 585), is called a *cortical arch*, the depth of which varies from a third to half an inch.

The *medullary substance*, as before stated, is seen to consist of pale red-colored, striated, conical masses, the *pyramids of Malpighi*, the number of which, varying from eight to eighteen, correspond to the number of lobes of which the organ in the foetal state is composed. The base of each pyramid is surrounded by a cortical arch, and directed toward the circumference of the kidney; the sides are contiguous with the cortical columns; whilst the apex, known as the *papilla* or *mammilla* of the kidney, projects into one of the calices of the ureter.

These two parts, *cortical* and *medullary*, so dissimilar in appearance, are very similar in structure, being made up of urinary tubes and blood-vessels united and bound together by a connecting matrix or stroma.

Minute Anatomy.—The *tubuli uriniferi*, of which the kidney is for the most part made up, commence in the cortical portion of the kidney, and, after pursuing a very circuitous course through the cortical and medullary parts of the kidney, finally terminate at the apices of the Malpighian pyramids by open mouths (Fig. 586), so that the fluid which they contain is emptied into the dilated extremity of the ureter contained in the sinus of the kidney. If the surface of one of the papillæ is examined with a lens, it will be seen to be studded over with a number of small depressions from sixteen to twenty in number, and in a fresh kidney, upon pressure being made, fluid will be seen to exude from these depressions. They are the orifices of the tubuli uriniferi, which terminate in this situation. They commence in the cortical portion of the kidney as the *Malpighian bodies*, which are small rounded masses, varying in size, but of an average of about $\frac{1}{120}$ of an inch in diameter. They are of a deep-red color, and are found only in the cortical portion of the kidney. Each of these little bodies is composed of two parts—a central glomerulus of vessels, called a *Malpighian tuft*, and a membranous envelope, the *Malpighian capsule*, or *capsule of Bowman*, which latter is a small pouch-like commencement of a uriniferous tubule.

The *Malpighian tuft*, or vascular glomerulus, is a network of convoluted capillary blood-vessels held together by scanty connective tissue and grouped into from two to five lobules. This capillary network is derived from a small arterial twig, the *afferent vessel*, which pierces the wall of the capsule, generally at a point opposite that at which the latter is connected with the tube; and the resulting vein, the *efferent vessel*, emerges from the capsule at the same point. The afferent vessel is usually the larger of the two (Fig. 587). The *Malpighian* or *Bowman's capsule*, which surrounds the glomerulus, is formed of a hyaline membrane supported by a small amount of connective tissue which is continuous with the connective tissue of the tube. It is lined on its inner surface by a layer of squa-

mous epithelial cells which are reflected from the lining membrane on to the glomerulus at the point of entrance or exit of the afferent and efferent vessels. The whole surface of the glomerulus is covered with a continuous layer of the same cells on a delicate supporting membrane, which with the cells dips in between the lobules of the glomerulus, closely surrounding them (Fig. 588). Thus, between the glomerulus and the capsule a space is left, forming a cavity lined by a continuous layer of cells, which varies in size according to the state of secretion and the amount of fluid present in it. The cells, as above stated, are squamous in

FIG. 587.—Minute structure of kidney.

FIG. 588.—Malpighian body.

the adult, but in the fœtus and young subject they are polyhedral or even columnar.

The *tubuli uriniferi*, commencing in the Malpighian bodies, in their course present many changes in shape and direction, and are contained partly in the medullary and partly in the cortical portions of the organ. At their junction with the Malpighian capsule they present a somewhat constricted portion which is termed the *neck*. Beyond this the tube becomes convoluted, and pursues a considerable course in the cortical structure, constituting the *proximal convoluted tube*. After a time the convolutions disappear, and the tube approaches the medullary portion of the kidney in a more or less spiral manner. This section of the tube has been called the *spiral tube of Schachowia*. Throughout this portion of their course the tubuli uriniferi have been contained entirely in the cortical structure, and have presented a pretty uniform calibre. They now enter the medullary portion, and suddenly become much smaller, quite straight in direction, and dip down for a variable depth into the pyramids, constituting the *descending limb of Henle's loop*. Bending on themselves, they form a kind of loop, the *loop of Henle*, and, reascending, become suddenly enlarged and again spiral in direction, forming the *ascending limb of Henle's loop*, and re-enter the cortical structure. This portion of the tube does not present a uniform calibre, but becomes narrower as it ascends and irregular in outline. As a narrow tube it enters the cortex and ascends for a short distance, when it again becomes dilated, irregular, and angular. This section is termed the *irregular tubule*; it terminates in a convoluted tube which exactly resembles the proximal convoluted tubule, and is called the *distal convoluted tubule*. This again terminates in a narrow *curved tube* which enters the straight or collecting tube.

Each *straight*, otherwise called a *collecting* or *receiving*, tube commences by a small orifice on the summit of one of the papillæ, thus opening and discharging its contents into the interior of one of the calices. Traced into the substance of the pyramid, these tubes are found to run from apex to base, dividing dichotomously in their course and slightly diverging from each other. Thus dividing and subdividing, they reach the base of the pyramid, and enter the cortical structure greatly increased in number. Upon entering the cortical portion they continue a straight course for a variable distance, and are arranged in groups called *medullary*

rays, several of these groups corresponding to a single pyramid. The tubes in the centre of the group are the longest, and reach almost to the surface of the kidney,

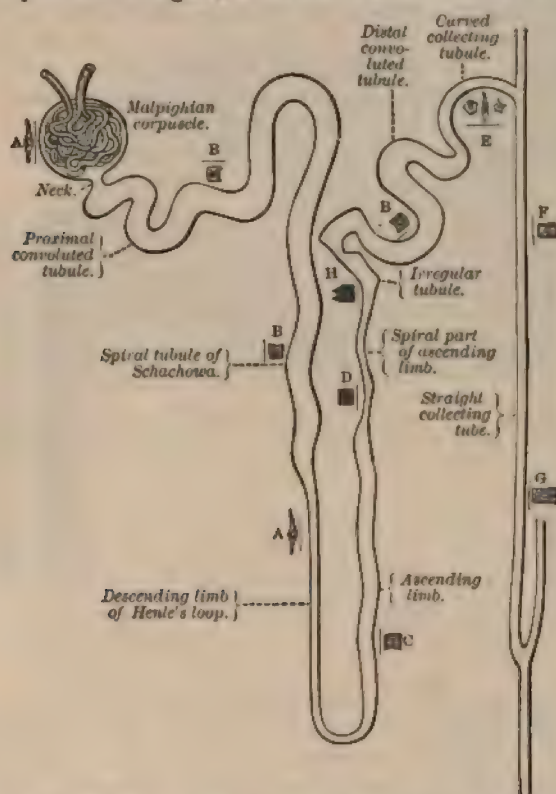

FIG. 389.—Uriniferous tube. For the sake of clearness the epithelial cells have been represented more highly magnified than the tubes in which they are contained.

while the external ones are shorter, and advance only a short distance into the cortex. In consequence of this arrangement the cortical portion presents a number of conical masses, the apices of which reach the periphery of the organ, and the bases are applied to the medullary portion. These are termed the *pyramids of Ferrein*. As they run through the cortical portion the straight tubes receive on either side the curved extremity of the convoluted tubes, which, as stated above, commence at the Malpighian bodies.

It will be seen from the above description that there is a continuous series of tubes from their commencement in the Malpighian bodies to their termination at the orifices on the apices of the pyramids of Malpighi, and that the urine, the secretion of which commences in the capsule, finds its way through these tubes into the calices of the kidney, and so into the ureter. Commencing at the capsule, the tube first presents a narrow constricted portion, (1) the *neck*. 2. It forms a wide convoluted tube, the *proximal convoluted tube*. 3. It becomes spiral, the *spiral tubule of Schachowia*. 4. It enters the medullary structure as a narrow, straight tube, the *descending limb of Henle's loop*. 5. Forming a loop and becoming dilated, it ascends somewhat spirally, and, gradually diminishing in calibre, again enters the cortical structure, the *ascending limb of Henle's loop*. 6. It now becomes irregular and angular in outline, the *irregular tubule*. 7. It then becomes convoluted, the *distal convoluted tubule*. 8. Diminishing in size, it forms a curve, the *curved tubule*. 9. Finally, it joins a straight tube, the *straight collecting tube*, which is continued downward through the medullary substance to open at the apex of a pyramid.

The Tubuli Uriniferi: their Structure.—The tubuli uriniferi consist of base-

ment membrane lined with epithelium. The epithelium varies considerably in different sections of the uriniferous tubes. In the neck the epithelium is continuous with that lining the Malpighian capsule, and, like it, consists of flattened cells with an oval nucleus (Fig. 589 A). The cells are, however, very indistinct and difficult to trace, and the tube has here the appearance of a simple basement membrane unlined by epithelium. In the proximal convoluted tubule and the spiral tubule of Schachowa the epithelium is polyhedral in shape, the sides of the cells not being straight, but fitting into each other, and in some animals so fused

together that it is impossible to make out the lines of junction. In the human kidney the cells often present an angular projection of the surface next the basement membrane. These cells are made up of more or less rod-like fibres, which rest by one extremity on the basement membrane, whilst the other projects toward the lumen of the tube. This gives to the cells the appearance of distinct striation (Heidenhain) (Fig. 589 B). In the descending limb of Henle's loop the epithelium resembles that found in the Malpighian capsule and the commencement of the tube, consisting of flat transparent epithelial plates with an oval nucleus (Figs. 589 A, 590). In the ascending limb, on the other hand, the cells partake more of the character of those described as existing in the proximal convoluted tubule, being polyhedral in shape and presenting the same appearance of striation. The nucleus, however, is not situated in the centre of the cell, but near the lumen (Fig. 589 c). After the ascending limb of Henle's loop becomes narrower upon entering the cortical structure, the striation appears to be confined to the outer part of the cell; at all events, it is much more distinct in this situation, the nucleus, which appears flattened and angular, being still situated near the lumen (Fig. 589 d). In the irregular tubule the cells undergo a still farther change, becoming very angular, and presenting thick bright rods or markings, which render the striation much more distinct than in any other section of the urinary tubules (Fig. 589 H). In the distal convoluted tubule the epithelium appears to be identical with that which has been described as existing in the proximal convoluted tubule (Fig. 589 B). In the curved tubule, just before its entrance into the straight collecting tube, the epithelium varies greatly as regards the shape of the cells, some being angular with short processes, others spindle-shaped, others polyhedral (Fig. 589 K).

In the straight tubes the epithelium is more or less columnar; in its papillary portion the cells are distinctly columnar and transparent (Figs. 591, 592), but as the tube approaches the cortex the cells are less uniform in shape; some are polyhedral, and others angular with short processes (Fig. 589 F and G).

The Renal Blood-vessels.—The kidney is plentifully supplied with blood by the renal artery, a large offset of the abdominal aorta. Previously to entering

the kidney, each artery divides into four or five branches, which are distributed to its substance. At the hilum these branches lie between the renal vein and ureter, the vein being usually in front, the ureter behind. Each vessel gives off some small branches to the suprarenal capsules, the ureter, and the sur-

rounding cellular tissue and muscles. Frequently there is a second renal artery, which is given off from the abdominal aorta at a lower level, and supplies the lower portion of the kidney. It is termed the *inferior renal artery*. The branches of the renal artery whilst in the sinus give off a few twigs for the nutrition of the surrounding tissues, and terminate in the *arteriae propriae renales*, which enter the kidney proper in the columns of Bertini. Two of these pass to each pyramid of Malpighi and run along its sides for its entire length,

giving off as they advance the afferent vessels of the Malpighian bodies in the columns. Having arrived at the bases of the pyramids, they make a bend in their course, so as to lie between the bases of the pyramids and the cortical arches, where they break up into two distinct sets of branches devoted to the supply of the remaining portions of the kidney.

The first set, the *interlobular arteries* (Figs. 593, 594 B), are given off at right

FIG. 595.—Diagrammatic representation of the blood-vessels in the substance of the cortex of the kidney. *m*, Region of the medullary ray. *b*, Region of the tortuous portion of the tubules. *ai*, Arteria interlobularis. *ri*, Vena interlobularis. *va*, Vas afferens. *gl*, Glomerulus. *re*, Vas efferens. *rz*, Venous twig of the interlobularis. (From Ludwig, in Stricker's *Handbook*.)

angles from the side of the arteriæ propriæ renales looking toward the cortical substance, and, passing directly outward between the pyramids of Ferrein, they reach the capsule, where they terminate in the capillary network of this part. In their outward course they give off lateral branches; these are the *afferent vessels* for the Malpighian bodies (see page 1014), and, having pierced the capsule, end in the Malpighian tufts. From each tuft the corresponding renal efferent arises, and, having made its egress from the capsule near to the point where the afferent vessel entered, anastomoses with other efferents from other tufts, and contributes to form a dense *venous plexus* around the adjacent urinary tubes (Fig. 595).

The second set of branches from the arteriæ propriæ renales are for the supply of the medullary pyramids, which they enter at their bases; and, passing straight through their substance to their apices, terminate in the venous plex-

uses found in that situation. They are called the *arterioli rectæ* (Figs. 593, 594 F).

The *Renal Veins* arise from three sources—the veins beneath the capsule, the plexuses around the tubuli contorti in the cortical arches, and the plexuses situated at the apices of the pyramids of Malpighi. The veins beneath the capsule are stellate in arrangement, and are derived from the capillary network of the capsule, into which the terminal branches of the interlobular arteries break up. These join to form the *venæ interlobulares*, which pass inward between the pyramids of Ferrein, receive branches from the plexuses around the tubuli contorti, and, having arrived at the bases of the Malpighian pyramids, join with the *venæ rectæ*, next to be described (Figs. 593, 594 b).

The *Venæ Rectæ* are branches from the plexuses at the apices of the medullary pyramids, formed by the terminations of the arterioli rectæ. They pass outward in a straight course between the tubes of the medullary structure, and joining, as above stated, the *venæ interlobulares*, form the proper renal veins (Figs. 593, 594 f).

These vessels, *Venæ Propriæ Renales*, accompany the arteries of the same name, running along the entire length of the sides of the pyramids; and, having received in their course the efferent vessels from the Malpighian bodies in the cortical structure adjacent, quit the kidney substance to enter the sinus. In this cavity they inosculate with the corresponding veins from the outer pyramids to form the *renal vein*, which emerges from the kidney at the hilum and opens into the inferior vena cava, the left being longer than the right, from having to cross in front of the abdominal aorta.

Nerves of the Kidney.—The nerves of the kidney, although small, are about fifteen in number. They have small ganglia developed upon them, and are derived from the renal plexus, which is formed by branches from the solar plexus, the lower and outer part of the semilunar ganglion and aortic plexus, and from the lesser and smallest splanchnic nerves. They communicate with the spermatic plexus, a circumstance which may explain the occurrence of pain in the testicle in affections of the kidney. So far as they have been traced, they seem to accompany

the renal artery and its branches, but their exact mode of termination is not known.

The *lymphatics* consist of a superficial and deep set which terminate in the lumbar glands.

Connective Tissue, or Intertubular Stroma.—Although the tubules and vessels are closely packed, a certain small amount of connective tissue, continuous with the capsule, binds them firmly together. This tissue was first described by Goodsir, and subsequently by Bowman. Ludwig and Zawarykin have observed distinct fibres passing around the Malpighian bodies, and Henle has seen them between the straight tubes composing the medullary structure.

Surface Form.—The kidneys, being situated at the back part of the abdominal cavity and deeply placed, cannot be felt unless enlarged or misplaced. They are situated on the confines of the epigastric and umbilical regions internally, with the hypochondriac and lumbar regions externally. The left is somewhat higher than the right. According to Morris, the position of the kidney may be thus defined: *Anteriorly*: "1. A horizontal line through the umbilicus is below the lower edge of each kidney. 2. A vertical line carried upward to the costal arch from the middle of Poupart's ligament has one-third of the kidney to its outer side and two-thirds to its inner side—*i. e.* between this line and the median line of the body." In adopting these lines it must be borne in mind that the axes of the kidneys are not vertical, but oblique, and if continued upward would meet about the ninth dorsal vertebra. *Posteriorly*: The upper end of the left kidney would be defined by a line drawn horizontally outward from the spinous process of the eleventh dorsal vertebra, and its lower end by a point two inches above the iliac crest. The right kidney would be half to three-quarters of an inch lower. Morris lays down the following rules for indicating the position of the kidney on the posterior surface of the body: "1. A line parallel with, and one inch from, the spine, between the lower edge of the tip of the spinous process of the eleventh dorsal vertebra and the lower edge of the spinous process of the third lumbar vertebra. 2. A line from the top of this first line outward at right angles to it for 2½ inches. 3. A line from the lower end of the first transversely outward for 2½ inches. 4. A line parallel to the first and connecting the outer extremities of the second and third lines just described."

The hilum of the kidney lies about two inches from the middle line of the back, at the level of the spinous process of the first lumbar vertebra.

Surgical Anatomy.—The kidney is imbedded in a large quantity of loose fatty tissue, and is but slightly covered by peritoneum; hence rupture of this organ is not nearly so serious an accident as rupture of the liver or spleen, since the extravasation of blood and urine which follows is outside the peritoneal cavity. Occasionally the kidney may be bruised by blows in the loin or by being compressed between the lower ribs and the ilium when the body is violently bent forward. This is followed by a little transient hæmaturia, which, however, speedily passes off. Occasionally, when rupture involves the pelvis of the kidney or the commencement of the ureter, this duct may become blocked, and hydronephrosis follow.

The loose cellular tissue around the kidney may be the seat of suppuration, constituting *perinephritic abscess*. This may be due to injury, to disease of the kidney itself, or to extension of inflammation from neighboring parts. It may burst into the pleura, constituting empyema; into the colon or bladder; or may point externally in the groin or loin. Tumors of the kidney, of which, perhaps, sarcoma in children is the most common, may be recognized by their position and fixity; by the resonant colon lying in front of it; by their not moving with respiration; and by their rounded outline, not presenting a notched anterior margin like the spleen, with which they are most likely to be confounded. The examination of the kidney should be bimanual; that is to say, one hand should be placed in the flank and firm pressure made forward, while the other hand is buried in the abdominal wall just external to the semilunar line. Manipulation of the kidney frequently produces a peculiar sickening sensation, with sometimes faintness.

The kidney is mainly held in position by the mass of fatty matter in which it is imbedded and over which the peritoneum is stretched. If this fatty matter is loose or lax or is absorbed, the kidney may become movable and may give rise to great pain. This condition occurs, therefore, in badly-nourished people or in those who have become emaciated from any cause, and is more common in women than in men. It must not be confounded with the *floating kidney*; this is a congenital condition due to the development of a meso-nephron, which permits the organ to move more or less freely. The two conditions cannot, however, be distinguished until the abdomen is opened or the kidney explored from the loin.

The kidney has, of late years, been frequently the seat of surgical interference. It may be exposed for exploration or the evacuation of pus (nephrotomy); it may be incised for the removal of stone (nephro-lithotomy); it may be sutured when movable or floating (nephrorraphy); or it may be removed (nephrectomy).

The kidney may be exposed either by a lumbar or abdominal incision. The lumbar operation is the one which is generally adopted, unless in cases of very large tumors or of wandering kidneys with a loose meso-nephron, on account of the advantages which it possesses of not opening the peritoneum and of affording admirable drainage. It may be performed either by an oblique, a vertical, or a transverse incision. Perhaps the preferable, as affording the best

means for exploring the whole surface of the kidney, is an incision from the tip of the last rib backward to the edge of the Erector spinæ. This incision must not be quite parallel to the rib, but its posterior end must be at least three-quarters of an inch below it, lest the pleura be wounded. This cut is quite sufficient for an exploration of the organ. Should it require removal, a vertical incision can be made downward to the crest of the ilium, along the outer border of the Quadratus lumborum. The structures divided are the skin, the superficial fascia with the cutaneous nerves, the deep fascia, the posterior border of the External oblique muscle of the abdomen, and the outer border of the Latissimus dorsi; the Internal oblique and the posterior aponeurosis of the Transversalis muscle; the outer border of the Quadratus lumborum, and the deep layer of the transversalis aponeurosis, and the transversalis fascia. The fatty tissue around the kidney is now exposed to view, and must be separated by the fingers or a director in order to reach the kidney.

The abdominal operation is best performed by an incision in the linea semilunaris on the side of the kidney to be removed, as recommended by Langenbuch. The incision is made of varying length according to the size of the kidney; its mid-point should be on a level with the umbilicus. The abdominal cavity is opened. The intestines are then held aside and the outer layer of the meso-colon opened, so that the fingers can be introduced behind the peritoneum and the renal vessels sought for. These are then to be ligatured; if tied separately, care must be taken to ligature the artery first. The kidney must now be enucleated, and the vessels and ureter divided, and the latter tied or, if thought necessary, stitched to the edge of the wound.

THE URETERS.

The **Ureters** are the two tubes which conduct the urine from the kidneys into the bladder. They commence within the sinus of the kidney by a number of short truncated branches, the *calices* or *infundibula*, which unite either directly or indirectly to form a dilated pouch, the *pelvis*, from which the ureter, after passing through the hilum of the kidney, descends to the bladder. The *calices* are cup-like tubes encircling the apices of the Malpighian pyramids; but inasmuch as one calyx may include two or even more papillæ, their number is generally less than the pyramids themselves, the former being from seven to thirteen, whilst the latter vary from eight to eighteen. These calices converge into two or three tubular divisions which by their junction form the *pelvis* or dilated portion of the ureter. The portion last mentioned, where the *pelvis* merges into the ureter proper, is found opposite the spinous process of the first lumbar vertebra, in which situation it is accessible behind the peritoneum (see Fig. 543, page 942).

The *ureter proper* is a cylindrical membranous tube, about sixteen inches in length and of the diameter of a goosequill, extending from the *pelvis* of the kidney to the bladder. Its course is obliquely downward and inward through the lumbar region into the cavity of the *pelvis*, where it passes downward, forward, and inward across that cavity to the base of the bladder, into which it then opens by a constricted orifice, after having passed obliquely for nearly an inch between its muscular and mucous coats.

Relations.—In its course it rests upon the Psoas muscle, being covered by the peritoneum, and crossed obliquely, from within outward, by the spermatic vessels; the right ureter lying close to the outer side of the inferior vena cava. Opposite the first piece of the sacrum it crosses either the common or external iliac artery, lying behind the ileum on the *right* side and the sigmoid flexure of the colon on the *left*. In the *pelvis* it enters the posterior false ligament of the bladder below the obliterated hypogastric artery, the vas deferens in the male passing between it and the bladder. In the female the ureter passes along the sides and cervix of the uterus and upper part of the vagina. At the base of the bladder it is situated about two inches from its fellow, lying, in the male, about an inch and a half behind the base of the prostate, at the posterior angle of the trigone.

Structure.—The *ureter* is composed of three coats—a fibrous, muscular, and mucous.

The *fibrous coat* is the same throughout the entire length of the duct, being continuous at one end with the capsule of the kidney at the floor of the sinus, whilst at the other it is lost in the fibrous structure of the bladder.

In the *pelvis* of the kidney the muscular coat consists of two layers, longitudinal and circular; the longitudinal fibres become lost upon the sides of the papillæ at

the extremities of the calices; the circular fibres may be traced surrounding the medullary structure in the same situation. In the ureter proper the muscular fibres are very distinct, and are arranged in three layers—an external longitudinal, a middle circular, and an internal layer, less distinct than the other two, but having a general longitudinal direction. According to Kölliker, this internal layer is only found in the neighborhood of the bladder.

The *mucous coat* is smooth, and presents a few longitudinal folds which become effaced by distension. It is continuous with the mucous membrane of the bladder below, whilst it is prolonged over the papillæ of the kidney above. Its epithelium is of a peculiar character, and resembles that found in the bladder. It is known by the name of “transitional” epithelium. It consists of several layers of cells, of which the innermost—that is to say, the cells in contact with the urine—are quadrilateral in shape, with a concave margin on their outer surface, into which fits the rounded end of the cells of the second layer. These, the intermediate cells, more or less resemble columnar epithelium, and are pear-shaped, with a rounded internal extremity which fits into the concavity of the cells of the first layer, and a narrow external extremity which is wedged in between the cells of the third layer. The external or third layer consists of conical or oval cells varying in number in different parts, and presenting processes which extend down into the basement membrane.

The *arteries* supplying the ureter are branches from the renal, spermatic, internal iliac, and inferior vesical.

The *nerves* are derived from the inferior mesenteric, spermatic, and pelvic plexuses.

THE SUPRARENAL CAPSULES.

The **Suprarenal Capsules** were formerly classified, together with the spleen, thymus, and thyroid, under the head of “ductless glands,” as they have no excretory duct. They are two small flattened glandular bodies, of a yellowish color, situated at the back part of the abdomen, behind the peritoneum and immediately in front of the upper part of each kidney; hence their name. The right one is somewhat triangular in shape, bearing a resemblance to a cocked hat; the left is more semilunar, and usually larger and higher than the right. They vary in size in different individuals, being sometimes so small as to be scarcely detected; their usual size is from an inch and a quarter to nearly two inches in length, rather less in width, and from two to three lines in thickness. Their average weight is about a drachm each.

Relations.—The relations of the suprarenal capsules differ on the two sides of the body. The *right suprarenal* presents on its anterior surface two areas: along its upper and inner borders a depressed area, which is in contact in front with the under surface of the right lobe of the liver, and along its inner border with the inferior vena cava (Rolleston), and behind rests on the crus of the Diaphragm; over the remainder of the anterior surface is an elevated area, which is covered in front by peritoneum passing from the upper part of the kidney to the under surface of the liver, and behind rests on the upper and inner part of the kidney. The *left suprarenal* is in contact by its anterior surface, superiorly, with the spleen; below and internal to this it is in contact with the peritoneum forming the lesser sac, which separates it from the cardiac extremity of the stomach; and at its lower part it is covered by the pancreas and splenic artery, and is therefore not in contact with the peritoneum. By its posterior surface, at its outer and back part, it rests upon the kidney, whilst below and internally it is in contact with the left crus of the Diaphragm. The surface of the suprarenal gland is surrounded by areolar tissue containing much fat, and closely invested by a thin fibrous coat, which is difficult to remove on account of the numerous fibrous processes and vessels which enter the organ through the furrows on its anterior surface and base.

Small accessory suprarenals are often to be found in the connective tissue

around the suprarenals. The smaller of these, on section, show a uniform surface, but in some of the larger a distinct medulla can be made out.

Structure.—On making a perpendicular section, the gland is seen to consist of two substances—external or cortical and internal or medullary. The former, which constitutes the chief part of the organ, is of a deep-yellow color. The medullary substance is soft, pulpy, and of a dark-brown or black color, whence the name *atrabilary capsules* formerly given to these organs. In the centre is often seen a space, not natural, but formed by the breaking down after death of the medullary substance.

FIG. 596.—Vertical section of the suprarenal capsule. From Elberth, in Stricker's *Manual*.

FIG. 597.

FIG. 598.

The **cortical portion** consists chiefly of narrow columnar masses placed perpendicularly to the surface. This arrangement is due to the disposition of the capsule, which sends into the interior of the gland processes passing in vertically and communicating with each other by transverse bands so as to form spaces which open into each other. These spaces are of slight depth near the surface of the organ, so that there the section somewhat resembles a net; this is termed the *zona glomerulosa*; but they become much deeper or longer farther in, so as to resemble pipes or tubes placed endwise, the *zona fasciculata*. Still deeper down, near the medullary part, the spaces become again of small extent; this is named the *zona reticularis*. These processes or trabeculae, derived from the capsule and forming the framework of the spaces, are composed of fibrous connective tissue with longitudinal bundles of unstriated muscular fibres. Within the interior of the spaces are contained groups of polyhedral cells, which are finely granular in appearance, and contain a spherical nucleus, and not unfrequently fat-molecules. These groups of cells do not entirely fill the spaces in which they are contained.

but between them and the trabeculae of the framework is a channel which is believed to be a lymph-path or sinus, and which communicates with certain passages between the cells composing the group. The lymph-path is supposed to open into a plexus of efferent lymphatic vessels which are contained in the capsule.

In the **medullary portion** the fibrous stroma seems to be collected together into a much closer arrangement, and forms bundles of connective tissue which are loosely applied to the large plexus of veins of which this part of the organ mainly consists. In the interstices lie a number of cells compared by Frey to those of columnar epithelium. They are coarsely granular, do not contain any fat-molecules, and some of them are branched. Luschka has affirmed that these branches are connected with the nerve-fibres of a very intricate plexus which is found in the medulla: this statement has not been verified by other observers, for the tissue of the medullary substance is less easy to make out than that of the cortical, owing to its rapid decomposition.

The numerous arteries which enter the suprarenal bodies from the sources mentioned below penetrate the cortical part of the gland, where they break up into capillaries in the fibrous septa, and these converge to the very numerous veins of the medullary portion, which are collected together into the suprarenal vein, which usually emerges as a single vessel from the centre of the gland.

The *arteries* supplying the suprarenal capsules are numerous and of large size; they are derived from the aorta, the phrenic, and the renal; they subdivide into numerous minute branches previous to entering the substance of the gland.

The *suprarenal vein* returns the blood from the medullary venous plexus, and receives several branches from the cortical substance; it opens on the right side into the inferior vena cava, on the left side into the renal vein.

The *lymphatics* terminate in the lumbar glands.

The *nerves* are exceedingly numerous: they are found chiefly, if not entirely, in the medulla, and are derived from the solar and renal plexuses, and, according to Bergmann, from the phrenic and pneumogastric nerves. They have numerous small ganglia developed upon them, from which circumstance the organ has been conjectured to have some function in connection with the sympathetic nervous system.

THE CAVITY OF THE PELVIS.

The **cavity of the pelvis** is that part of the general abdominal cavity which is below the level of the linea ilio-pectinea and the promontory of the sacrum.

Boundaries.—It is bounded behind by the sacrum, the coccyx, the Piriformis muscle, and the great sacro-sciatic ligaments; in front and at the sides by the ossa pubis and ischia, covered by the Obturator muscles; above, it communicates with the cavity of the abdomen; and below, the outlet is closed by the triangular ligament, the Levatores ani and Coccygei muscles, and the visceral layer of the pelvic fascia, which is reflected from the wall of the pelvis on to the viscera.

Contents.—The viscera contained in this cavity are—the urinary bladder, the rectum, and some of the generative organs peculiar to each sex, and some convolutions of the small intestines; they are partially covered by the peritoneum, and supplied with blood-vessels, lymphatics, and nerves.

THE BLADDER.

The **bladder** is the reservoir for the urine. It is a musculo-membranous sac situated in the pelvis, behind the pubes, and in front of the rectum in the male, the uterus and vagina intervening between it and that intestine in the female. The shape, position, and relations of the bladder are greatly influenced by age, sex, and the degree of distension of the organ. *During infancy* it is conical in shape, and projects above the upper border of the os pubis into the hypogastric region. *In the adult*, when quite empty and contracted, it is a small triangular

cord, the obliterated portion of the hypogastric artery, which, passing upward from the side of the bladder, approaches the urachus above its summit. In the infant, at birth, it is occasionally found pervious, so that the urine escapes at the umbilicus, and calculi have been found in its canal.

The *body of the bladder* is not covered in front by peritoneum, but is in relation with the triangular ligament, the posterior surface of the symphysis pubis, the Internal obturator muscles, and, when distended, with the abdominal parietes.

The posterior surface is covered by peritoneum. It corresponds, in the male, with the rectum; in the female, with the uterus, some convolutions of the small intestine being interposed.

The side of the bladder is crossed obliquely from below, upward and forward,

FIG. 690.—Frontal section of the lower part of the abdomen. Viewed from the front. (Braune.)

by the obliterated hypogastric artery; above and behind this cord the bladder is covered by peritoneum, but below and in front of it the serous covering is wanting, and it is connected to the pelvic fascia. The vas deferens passes, in an arched direction, from before backward, along the side of the bladder, toward its base, crossing in its course the obliterated hypogastric artery, and passing along the inner side of the ureter.

The *base (fundus)* of the bladder is directed downward and backward. It varies in extent according to the state of distension of the organ, being very broad when full, but much narrower when empty. In the male it rests upon the second portion of the rectum, from which it is separated by a reflection of the recto-vesical fascia. It is covered posteriorly, for a slight extent, by the peritoneum, which is reflected from it upon the rectum, forming the recto-vesical fold. The portion of the bladder in relation with the rectum corresponds to a triangular space bounded

in front by the prostate gland, behind by the recto-vesical fold of the peritoneum, and on each side by the vesicula seminalis and vas deferens. It is separated from direct contact with the rectum by the recto-vesical fascia. When the bladder is very full the peritoneal fold is raised with it, and the distance between its reflection and the anus is about four inches; but this distance is much diminished when the bladder is empty and contracted. *In the female* the base of the bladder lies in contact with the lower part of the cervix uteri, is adherent to the anterior wall of the vagina, and separated from the upper part of the anterior surface of the cervix uteri by a fold of the peritoneum.

The so-called *neck (cervix) of the bladder* is the point of commencement of the urethra; there is, however, no tapering part, which would constitute a true

FIG. 601.—Vertical median section of the male pelvis. (Hendle.)

neck, but the bladder suddenly contracts to the opening of the urethra. In the male its direction is oblique in the erect posture, and it is surrounded by the prostate gland. In the female its direction is obliquely downward and forward.

Ligaments.—The bladder is retained in its place by ligaments which are divided into true and false. The true ligaments are five in number: two anterior, two lateral, and the urachus. The false ligaments, also five in number, are formed by folds of the peritoneum.

The *anterior ligaments (pubo-prostatic)* extend from the back of the os pubis, one on each side of the symphysis, to the front of the neck of the bladder, over the upper surface of the prostate gland. These ligaments are formed by the recto-vesical fascia, and contain a few muscular fibres prolonged from the bladder.

The *lateral ligaments*, also formed by the recto-vesical fascia, are broader and thinner than the preceding. They are attached to the lateral parts of the prostate and to the sides of the base of the bladder.

The *urachus* is the fibro-muscular cord already mentioned, extending between the summit of the bladder and the umbilicus. It is broad below, at its attachment to the bladder, and becomes narrower as it ascends.

The *false ligaments of the bladder* are—two posterior, two lateral, and one superior.

The *two posterior* pass forward, in the male, from the sides of the rectum; in the female, from the sides of the uterus to the posterior and lateral aspect of the bladder; they form the lateral boundaries of the recto-vesical fold of the peritoneum, and contain the obliterated hypogastric arteries and the ureters, together with vessels and nerves.

The *two lateral ligaments* are reflections of the peritoneum from the iliac fossæ to the sides of the bladder.

The *superior ligament* is the prominent fold of peritoneum extending from the summit of the bladder to the umbilicus. It covers the urachus and the obliterated hypogastric arteries.

Structure.—The bladder is composed of four coats—serous, muscular, submucous, and mucous.

The *serous coat* is partial, and derived from the peritoneum. It invests the posterior surface, from opposite the termination of the two ureters to its summit, and is reflected from this point and from the sides on to the abdominal and pelvic walls.

The *muscular coat* consists of three layers of unstriated muscular fibre: an external layer, composed of fibres having for the most part a longitudinal arrangement; a middle layer, in which the fibres are arranged, more or less, in a circular manner; and an internal layer, in which the fibres have a general longitudinal arrangement.

The *fibres of the external longitudinal layer* arise from the posterior surface of the body of the os pubis in both sexes (*musculi pubo-vesicalis*), and in the male from the adjacent part of the prostate gland and its capsule. They pass, in a more or less longitudinal manner, up the anterior surface of the bladder, over its apex, and then descend along its posterior surface to its base, where they become attached to the prostate in the male and to the front of the vagina in the female. At the sides of the bladder the fibres are arranged obliquely and intersect one another. This layer has been named the *detrusor urinæ muscle*.

The *middle circular layers* are very thinly and irregularly scattered on the body of the organ, and, though to some extent placed transversely to the long axis of the bladder, are for the most part arranged obliquely. Toward the lower part of the bladder, round the cervix and commencement of the urethra, they are disposed in a thick circular layer, forming the *sphincter vesicæ*, which is continuous with the muscular fibres of the prostate gland.

The *internal longitudinal layer* is thin, and its fasciculi have a reticular arrangement, but with a tendency to assume for the most part a longitudinal direction.

Two bands of oblique fibres, originating behind the orifices of the ureters, converge to the back part of the prostate gland, and are inserted, by means of a fibrous process, into the middle lobe of that organ. They are the *muscles of the ureters*, described by Sir C. Bell, who supposed that during the contraction of the bladder they served to retain the oblique direction of the ureters, and so prevent the reflux of the urine into them.

The *submucous coat* consists of a layer of areolar tissue connecting together the muscular and mucous coats, and intimately united to the latter.

The *mucous coat* is thin, smooth, and of a pale rose color. It is continuous through the ureters with the lining membrane of the uriniferous tubes, and below with that of the urethra. It is connected loosely to the muscular coat by a layer

of areolar tissue, excepting at the trigone, where its adhesion is more close. It is provided with a few mucous follicles, and numerous small racemose glands lined with columnar epithelium exist near the neck of the organ. The epithelium covering it is of the transitional variety, consisting of a superficial layer of polyhedral, flattened cells, each with one, two, or three nuclei; beneath these a stratum of large club-shaped cells, with the narrow extremity directed downward

FIG. 602.—Superficial layer of the epithelium of the bladder. Composed of polyhedral cells of various sizes, each with one, two, or three nuclei. (Klein and Noble Smith.)

FIG. 603.—Deep layers of epithelium of bladder showing large club-shaped cells above, and smaller, more spindle-shaped cells below, each with an oval nucleus. (Klein and Noble Smith.)

and wedged in between smaller spindle-shaped cells, containing an oval nucleus (Figs. 602, 603).

Objects Seen on the Inner Surface.—Upon the inner surface of the bladder are seen the orifices of the ureters, the trigone, and the commencement of the urethra.

The Orifices of the Ureters.—These are situated at the base of the trigone, being distant from each other by about two inches; they are about an inch and a half from the base of the prostate and the commencement of the urethra.

The *trigonum vesicæ*, or *trigone vesical*, is a triangular smooth surface, with the apex directed forward, situated at the base of the bladder immediately behind the urethral orifice. It is paler in color than the rest of the mucous membrane, and never presents any rugæ, even in the collapsed condition of the organ, owing to its intimate adhesion to the subjacent tissue. It is bounded at each posterior angle by the orifices of the ureters, which are placed nearly two inches from each other and about an inch and a half behind the orifice of the urethra. The trigone corresponds with the interval at the base of the bladder, bounded by the prostate in front and the vesiculæ seminales and vasa deferentia on the sides. Projecting from the lower and anterior part of the bladder into the orifice of the urethra is a slight elevation of mucous membrane called the *uvula vesicæ*. It is formed by a thickening of the submucous tissue.

The *arteries* supplying the bladder are the superior, middle, and inferior vesical in the male, with additional branches from the uterine and vaginal in the female. They are all derived from the anterior trunk of the internal iliac. The obturator and sciatic arteries also supply small visceral branches to the bladder.

The *veins* form a complicated plexus round the neck, sides, and base of the bladder, and terminate in the internal iliac vein.

The *lymphatics* accompany the blood-vessels, passing through the glands surrounding them.

The *nerves* are derived from the pelvic plexus of the sympathetic and from the third and the fourth sacral nerves; the former supplying the upper part of the organ, the latter its base and neck. According to F. Darwin, the sympathetic fibres have ganglia connected with them, which send branches to the vessels and muscular coat.

Surface Form.—The surface form of the bladder varies with its degree of distension and under other circumstances. In the young child it is represented by a conical figure, the apex

of which, even when the viscus is empty, is situated in the hypogastric region, about an inch above the level of the symphysis pubis. In the adult, when the bladder is empty, its apex does not reach above the level of the upper border of the symphysis pubis, and the whole organ is situated in the pelvis; the neck, in the male, corresponding to a line drawn horizontally backward through the symphysis a little below its middle. As the bladder becomes distended it gradually rises out of the pelvis into the abdomen, and forms a swelling in the hypogastric region which is perceptible to the hand as well as to percussion. In extreme distension it reaches into the umbilical region. Under these circumstances it is closely applied to the abdominal wall, without the intervention of peritoneum, so that it can be tapped by an opening in the middle line just above the pubes without any fear of wounding the serous membrane. When the rectum is distended the prostatic portion of the urethra is elongated and the bladder lifted out of the pelvis and the peritoneum pushed upward. Advantage is taken of this in performing the operation of suprapubic cystotomy. The rectum is distended by an india-rubber bag, which is introduced into this cavity empty, and then filled with ten or twelve ounces of water. If now the bladder is injected with about half a pint of some antiseptic fluid, it will appear above the pubes, plainly perceptible to the sight and touch. The peritoneum will be pushed out of the way, and an incision three inches long may be made in the linea alba from the symphysis pubis upward without any great risk of wounding the peritoneum.

When distended the bladder can be felt in the male, from the rectum, behind the prostate, and fluctuation can be perceived by a bimanual examination, one finger being introduced into the rectum and the distended bladder tapped on the front of the abdomen with the finger of the other hand. This portion of the bladder—that is, the portion felt in the rectum by the finger—is also uncovered by peritoneum, and the bladder may here be punctured from the rectum, in the middle line, without risk of wounding the serous membrane.

Surgical Anatomy.—A defect of development in which the bladder is implicated is known under the name of *extroversion of the bladder*. In this condition the lower part of the abdominal wall and the anterior wall of the bladder are wanting, so that the posterior surface of the bladder presents on the abdominal surface, and is pushed forward by the pressure of the viscera within the abdomen, forming a red vascular tumor on which the openings of the ureters are visible. The penis, except the glans, is rudimentary and is cleft on its dorsal surface, exposing the floor of the urethra—a condition known as *epispadias*. The pelvic bones are also arrested in development (see page 285).

The bladder may be ruptured by violence applied to the abdominal wall, when the viscus is distended without any injury to the bony pelvis, or it may be torn in cases of fracture of the pelvis. The rupture may be either intraperitoneal or extraperitoneal—that is, may implicate the posterior surface of the bladder in the former case, or the anterior surface in the latter. Rupture of the anterior surface alone is, however, very rare. Until recently intraperitoneal rupture was uniformly fatal, but now abdominal section and suturing the rent with Lembert's suture is resorted to, with a very considerable amount of success. The sutures are inserted only through the peritoneal and muscular coats in such a way as to bring the serous surfaces at the margins of the wound into apposition, and one is inserted just beyond each end of the wound. The bladder should be tested as to whether it is water-tight before closing the external wound.

The muscular coat of the bladder undergoes hypertrophy in cases in which there is any obstruction to the flow of urine. Under these circumstances the bundles of which the muscular coat consists become much increased in size, and, interlacing in all directions, give rise to what is known as the *fasciculated bladder*. Between these bundles of muscular fibres the mucous membrane may bulge out, forming sacculi, constituting the *sacculated bladder*, and in these little pouches phosphatic secretions may collect, forming *encysted calculi*. The mucous membrane is very loose and lax, except over the trigone, to allow of the distension of the viscus.

Various forms of tumor have been found springing from the wall of the bladder. The

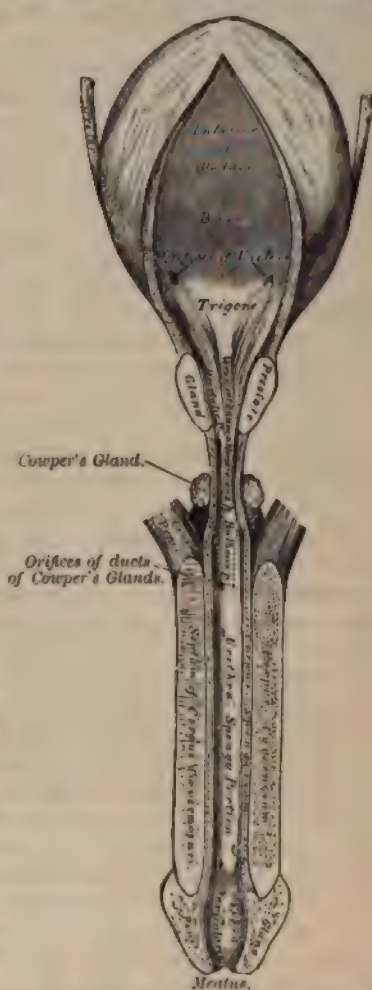

FIG. 604.—The bladder and urethra laid open. Seen from above.

innocent tumors are the papilloma and the mucous polypus, arising from the mucous membrane; the fibrous, from the submucous tissue; and the myoma, originating in the muscular tissue, and, very rarely, dermoid tumors, the exact origin of which it is difficult to explain. Of the malignant tumors, epithelioma is the most common, but sarcomata are occasionally found in the bladder of children.

Puncture of the bladder may be performed either above the pubes or through the rectum, in both cases without wounding the peritoneum. The former plan is generally to be preferred, since in puncture by the rectum a permanent fistula may be left from abscess forming between the rectum and the bladder; or pelvic cellulitis may be set up; moreover, it is exceedingly inconvenient to keep a cannula in the rectum. In some cases in performing this operation the recto-vesical pouch of peritoneum has been wounded, inducing fatal peritonitis. The operation, therefore, has been almost completely abandoned.

THE MALE URETHRA.

The **urethra in the male** extends from the neck of the bladder to the meatus urinarius. It presents a double curve in the flaccid state of the penis, but in the erect state it forms only a single curve, the concavity of which is directed upward (Fig. 599). Its length varies from eight to nine inches, and it is divided into three portions, the *prostatic*, *membranous*, and *spongy*, the structure and relations of which are essentially different. Except during the passage of the urine or semen the urethra is a mere transverse cleft or slit, with its upper and under surfaces in contact. At the orifice of the urethra at the end of the penis the slit is vertical, and in the prostatic portion somewhat arched.

The **Prostatic Portion** is the widest and most dilatable part of the canal. It passes through the prostate gland, from its base to its apex, lying nearer its upper than its lower surface. It is about an inch and a quarter in length; the form of the canal is spindle-shaped, being wider in the middle than at either extremity, and narrowest in front, where it joins the membranous portion. A transverse section of the canal as it lies in the prostate is horseshoe in shape, the convexity being directed upward (Fig. 605).

Upon the floor of the canal is a narrow longitudinal ridge, the *verumontanum*, or *caput gallinaginis*, formed by an elevation of the mucous membrane and its subjacent tissue. It is eight or nine lines in length and a line and a half in height, and contains, according to Kobelt, muscular and erectile tissues. When distended it may serve to prevent the passage of the semen backward into the bladder. On each side of the verumontanum is a slightly depressed fossa, the *prostatic sinus*, the floor of which is perforated by numerous apertures, the *orifices of the prostatic ducts*, the ducts of the middle lobe opening behind the verumontanum. At the fore part of the verumontanum, in the middle line, is a depression, the *sinus pocularis* (*vesicula prostatica*), and upon or within its margins are the slit-like openings of the ejaculatory ducts. The sinus pocularis forms a *cul-de-sac* about a quarter of an inch in length, which runs upward and backward in the substance of the prostate beneath the middle lobe; its prominent upper wall partly forms the verumontanum. Its walls are composed of fibrous tissue, muscular fibres, and mucous membrane, and numerous small glands open on its inner surface. It has been called by Weber, who discovered it, the *uterus masculinus*, from its being developed from the united ends of the rudimentary Müllerian ducts, and therefore homologous with the uterus in the female.

The **Membranous portion of the urethra** extends between the apex of the prostate and the bulb of the corpus spongiosum. It is the narrowest part of the canal (excepting the orifice), and measures three-quarters of an inch along its upper and half an inch along its lower surface, in consequence of the bulb projecting backward beneath it. Its upper concave surface is placed about an inch beneath the pubic arch, from which it is separated by the dorsal vessels and nerves of the penis and some muscular fibres. Its lower convex surface is separated from the rectum by a triangular space, which constitutes the perineum. The membranous portion of the urethra perforates both the anterior and posterior layers of the deep perineal fascia, and receives an investment from them. As it pierces the posterior layer, the fibres around the opening are prolonged backward

over the posterior part of the membranous portion of the urethra, and as it pierces the anterior layer, a similar prolongation takes place in the opposite direction, investing the anterior part of the membranous portion. It is also surrounded by the Compressor urethræ muscle.

The **Spongy portion** is the longest part of the urethra, and is contained in the corpus spongiosum. It is about six inches in length, and extends from the termination of the membranous portion to the meatus urinarius. Commencing below the symphysis pubis, it ascends for a short distance and then curves downward. It is narrow and of uniform size in the body of the penis, measuring about a quarter of an inch in diameter, being dilated behind, within the bulb, and again anteriorly within the glans penis, where it forms the *fossa navicularis*.

The *Bulbous portion* is a name given, in some descriptions of the urethra, to the posterior part of the spongy portion contained within the bulb.

The *meatus urinarius* is the most contracted part of the urethra; it is a vertical slit, about three lines in length, bounded on each side by two small labia.

The inner surface of the lining membrane of the urethra, especially on the floor of the spongy portion, presents the orifices of numerous mucous glands and follicles situated in the submucous tissue, and named the *glands of Littre*. They vary in size, and their orifices are directed forward, so that they may easily intercept the point of a catheter in its passage along the canal. One of these lacunæ, larger than the rest, is situated in the upper surface of the fossa navicularis, about an inch and a half from the orifice; it is called the *lacuna magna*. Into the bulbous portion are found opening the ducts of Cowper's glands.

Structure.—The urethra is composed of a continuous mucous membrane, supported by a submucous tissue which connects it with the various structures through which it passes.

The *mucous coat* forms part of the genito-urinary mucous membrane. It is continuous with the mucous membrane of the bladder, ureters, and kidneys; externally with the integument covering the glans penis; and is prolonged into the ducts of the glands which open into the urethra—viz. Cowper's glands and the prostate gland—and into the vasa deferentia and vesiculæ seminales through the ejaculatory ducts. In the spongy and membranous portions the mucous membrane is arranged in longitudinal folds when the organ is contracted. Small papillæ are found upon it near the orifice, and its epithelial lining is of the columnar variety, excepting near the meatus, where it is squamous.

The *submucous tissue* consists of a vascular erectile layer, outside which is a layer of unstriped muscular fibres, arranged in a circular direction, which separates the mucous membrane and submucous tissue from the tissue of the corpus spongiosum.

Surgical Anatomy.—The urethra may be ruptured by the patient falling astride of any hard substance and striking his perineum, so that the urethra is crushed against the pubic arch. Bleeding will at once take place from the urethra, and this, together with the bruising in the perineum and the history of the accident, will at once point to the nature of the injury.

The surgical anatomy of the urethra is of considerable importance in connection with the passage of instruments into the bladder. Otis was the first to point out that the urethra is capable of great dilatibility, so that, excepting through the external meatus, an instrument corresponding to 18 English gauge (29 French) can usually be passed without damage. The orifice of the urethra is not so dilatable, and therefore frequently requires slitting. A recognition of this dilatibility caused Bigelow to very considerably modify the operation of lithority and introduce that of litholapaxy. In passing catheters, especially fine ones, the point of the instrument should be kept as far as possible along the upper wall of the canal, as the point is otherwise very liable to enter one of the lacunæ. Stricture of the urethra is a disease of very common occurrence, and is generally situated in the spongy portion of the urethra, most commonly in the bulbous portion, just in front of the membranous urethra, but in a very considerable number of cases in the penile or ante-serotal part of the canal.

THE PROSTATE GLAND.

THE Prostate Gland (*πρωστάτη*, to stand before) is a pale, firm, glandular which is placed immediately in front of the neck of the bladder and at the commencement of the urethra. It is placed in the pelvic cavity, behind below the symphysis pubis, posterior to the deep perineal fascia, and rests upon

FIG. 605.—Transverse section of the prostate gland showing the urethra, with the eminentia of the caput glandulae; beneath it the sinus prostaticus and ejaculatory ducts.

rectum, through which it may be distinctly felt, especially when enlarged. shape and size it resembles a chestnut.

Its *base* is directed backward toward the neck of the bladder.

Its *apex* is directed forward to the deep perineal fascia, which it touches.

Its *under surface* is smooth, marked by a slight longitudinal furrow, and

gland; and by the anterior portion of the Levator ani muscle (*levator prostatae*), which passes down on each side from the symphysis pubis and anterior ligament of the bladder to the sides of the prostate.

The prostate consists of two lateral lobes and a middle lobe.

The *two lateral lobes* are of equal size, separated by a deep notch behind, and by a slight furrow upon their upper and lower surfaces, which indicates the bilobed condition of the organ in some animals.

The third, or *middle lobe*, is a small transverse band, occasionally a rounded or triangular prominence, placed between the two lateral lobes at the posterior part of the organ. It lies immediately beneath the neck of the bladder, behind the commencement of the urethra, and above and between the ejaculatory ducts. Its existence is not constant, but it is occasionally found at an early period of life, as well as in adults and in old age.

The prostate gland is perforated by the urethra and the ejaculatory ducts. The urethra usually lies about one-third nearer its upper than its lower surface; occasionally, the prostate surrounds only the lower three-fourths of this tube, and more rarely the urethra runs through the lower instead of the upper part of the gland. The ejaculatory ducts pass forward obliquely through the lower part of the prostate and open into the prostatic portion of the urethra.

Structure.—The prostate is enclosed in a thin but firm fibrous capsule, distinct from that derived from the posterior layer of the deep perineal fascia, and separated from it by a plexus of veins. Its substance is of a pale reddish-gray color, of great density and not easily torn. It consists of glandular substance and muscular tissue.

The muscular tissue, according to Kölliker, constitutes the proper stroma of the prostate, the connective tissue being very scanty, and simply forming thin trabeculae between the muscular fibres, in which the vessels and nerves of the gland ramify. The muscular tissue is arranged as follows: Immediately beneath the fibrous capsule is a dense layer, which forms an investing sheath for the gland; secondly, around the urethra, as it lies in the prostate, is another dense layer of circular fibres, continuous behind with the internal layer of the muscular coat of the bladder, and in front blending with the fibres surrounding the membranous portion of the urethra. Between these two layers strong bands of muscular tissue, which decussate freely, form meshes in which the glandular structure of the organ is imbedded. In that part of the gland which is situated above the urethra the muscular tissue is especially dense, and there is here little or no gland tissue; while in that part which is below the urethra the muscular tissue presents a wide-meshed structure, which is densest at the upper part of the gland—that is, near the bladder—becoming looser and more sponge-like toward the apex of the organ.

The *glandular substance* is composed of numerous follicular pouches, opening into elongated canals, which join to form from twelve to twenty small excretory ducts. The follicles are connected together by areolar tissue, supported by prolongations from the fibrous capsule and muscular stroma, and enclosed in a delicate capillary plexus. The epithelium lining of both the canals and the terminal vesicles is of the columnar variety. The prostatic ducts open into the floor of the prostatic portion of the urethra.

Vessels and Nerves.—The *arteries* supplying the prostate are derived from the internal pudic, vesical, and hæmorrhoidal. Its *veins* form a plexus around the sides and base of the gland; they receive in front the dorsal vein of the penis, and terminate in the internal iliac vein. The *nerves* are derived from the pelvic plexus.

Surgical Anatomy.—The relation of the prostate to the rectum should be noted: by means of the finger introduced into the gut the surgeon detects enlargement or other disease of this organ; he can feel the apex of the gland, which is the guide to Cock's operation for stricture; he is enabled also by the same means to direct the point of a catheter when its introduction is attended with difficulty either from injury or disease of the membranous or prostatic portions of

the urethra. When the finger is introduced into the bowel the surgeon may, in some cases, especially in boys, learn the position, as well as the size and weight, of a calculus in the bladder, and in the operation for its removal, if, as is not unfrequently the case, it should be lodged behind an enlarged prostate, it may be displaced from its position by pressing upward the base of the bladder from the rectum. The prostate gland is occasionally the seat of suppuration, either due to injury, gonorrhœa, or tuberculous disease. The gland, being enveloped in a dense unyielding capsule, determines the course of the abscess, and also explains the great pain which is present in the acute form of the disease. The abscess most frequently bursts into the urethra, the direction in which there is least resistance, but may occasionally burst into the rectum, or more rarely in the perineum. In advanced life the prostate becomes considerably enlarged, and projects into the bladder so as to impede the passage of the urine. According to Dr. Messer's researches, conducted at Greenwich Hospital, it would seem that such obstruction exists in 20 per cent. of all men over sixty years of age. In some cases the enlargement affects principally the lateral lobes, which may undergo considerable enlargement without causing much inconvenience. In other cases it would seem that the middle lobe enlarges most, and even a small enlargement of this lobe may act injuriously, by forming a sort of valve over the urethral orifice, preventing the passage of the urine, and blocking more completely the orifice the more the patient strains. In consequence of the enlargement of the prostate a pouch is formed at the base of the bladder behind the projection, in which water collects and cannot be entirely expelled. It becomes decomposed and ammoniacal, and leads to cystitis. For this condition "prostatectomy" is sometimes done. The bladder is opened by an incision above the symphysis pubis, the mucous membrane incised, and the enlarged and projecting middle lobe enucleated.

COWPER'S GLANDS.

Cowper's Glands are two small rounded and somewhat lobulated bodies of a yellow color, about the size of peas, placed beneath the fore part of the membranous portion of the urethra, between the two layers of the deep perineal fascia. They lie close behind the bulb, and are enclosed by the transverse fibres of the Compressor urethrae muscle. Their existence is said to be constant: they gradually diminish in size as age advances.

Structure.—Each gland consists of several lobules held together by a fibrous investment. Each lobule consists of a number of acini lined by columnar epithelial cells, opening into one duct, which, joining with the ducts of other lobules outside the gland, form a single excretory duct. The excretory duct of each gland, nearly an inch in length, passes obliquely forward beneath the mucous membrane, and opens by a minute orifice on the floor of the bulbous portion of the urethra. Their existence is said to be constant; they gradually diminish in size as age advances.

THE PENIS.

The **Penis** is the organ of copulation. It consists of a root, body, and extremity, or *glans penis*.

The *root* is firmly connected to the rami of the os pubis and ischium by two strong tapering, fibrous processes, the *crura*, and to the front of the symphysis pubis by the *suspensory ligament*, a strong band of fibrous tissue which passes downward from the front of the symphysis pubis to the upper surface of the root of the penis, where it blends with the fascial sheath of the organ.

The *extremity* or *glans penis*, presents the form of an obtuse cone, flattened from above downward. At its summit is a vertical fissure, the orifice of the urethra (*meatus urinarius*). The base of the glans forms a rounded projecting border, the *corona glandis*, and behind the corona is a deep constriction, the *corvix*. Upon both of these parts numerous small sebaceous glands are found, the *glandula Tysonii odorifera*. They secrete a sebaceous matter of very peculiar odor, which probably contains caseine and becomes easily decomposed.

The *body* of the *penis* is the part between the root and extremity. In the flaccid condition of the organ it is cylindrical, but when erect has a triangular prismatic form with rounded angles, the broadest side being turned upward, and called the *dorsum*. The body is covered by integument, and contains in its interior a large portion of the urethra. The integument covering the penis is remarkable for its thinness, its dark color, its looseness of connection with the deeper parts of the organ, and its containing no adipose tissue. At the root of the penis the

integument is continuous with that upon the pubes and scrotum, and at the neck of the glans it leaves the surface and becomes folded upon itself to form the *prepuce*.

The internal layer of the prepuce is attached behind to the cervix, and approaches in character to a mucous membrane; from the cervix it is reflected over the glans penis, and at the meatus urinarius is continuous with the mucous lining of the urethra.

The mucous membrane covering the glans penis contains no sebaceous glands, but projecting from its free surface are a number of small, highly sensitive papillae. At the back part of the meatus urinarius a fold of mucous membrane passes backward to the bottom of a depressed raphe, where it is continuous with the prepuce; this fold is termed the *frœnum præputii*.

Structure of the Penis.—The penis is composed of a mass of erectile tissue enclosed in three cylindrical fibrous compartments. Of these, two, the *corpora cavernosa*, are placed side by side along the upper part of the organ; the third, or *corpus spongiosum*, encloses the urethra and is placed below.

The **Corpora Cavernosa** form the chief part of the body of the penis. They consist of two fibrous cylindrical tubes, placed side by side, and intimately connected along the median line for their anterior three-fourths, whilst at their back part they separate from each other to form the *crura*, which are two strong tapering fibrous processes firmly connected to the rami of the os pubis and ischium. Each crus commences by a blunt-pointed process in front of the tuberosity of the ischium, and before its junction with its fellow to form the body of the penis it presents a slight enlargement, named by Kobelt the *bulb of the corpus cavernosum*. Just beyond this point they become constricted, and retain an equal diameter to their anterior extremity, where they form a single rounded end which is received into a fossa in the base of the glans penis. A median groove on the upper surface lodges the dorsal vein of the penis, and the groove on the under surface receives the corpus spongiosum. The root of the penis is connected to the symphysis pubis by the suspensory ligament.

Structure.—The corpora cavernosa are surrounded by a strong fibrous envelope, consisting of two sets of fibres—the one, longitudinal in direction, being common to the two corpora cavernosa, and investing them in a common covering; the other, internal, being circular in direction, and being proper to each corpus cavernosum. The internal circular fibres by their junction at one part form an incomplete partition or septum between the two bodies.

The *septum* between the two corpora cavernosa forms an imperfect partition; it is thick and complete behind, but in front it is incomplete, and consists of a number of vertical bands, which are arranged like the teeth of a comb, whence the name which it has received, *septum pectiniforme*. These bands extend between the dorsal and the urethral surface of the corpora cavernosa. This fibrous investment is extremely dense, of considerable thickness, and consists of bundles of shining white fibres, with an admixture of well-developed elastic fibres, so that it is possessed of great elasticity.

From the internal surface of the fibrous envelope, as well as from the sides of the septum, are given off a number of bands or cords which cross the interior of the corpora cavernosa in all directions, subdividing them into a number of separate compartments, and giving the entire structure a spongy appearance. These bands and cords are called *trabeculae*, and consist of white fibrous tissue, elastic fibres, and plain muscular fibres. In them are contained numerous arteries and nerves.

The component fibres of which the trabeculae are composed are larger and stronger round the circumference than at the centre of the corpora cavernosa; they are also thicker behind than in front. The interspaces, on the contrary, are larger at the centre than at the circumference, their long diameter being directed transversely; they are largest anteriorly. They are occupied by venous blood, and are lined by a layer of flattened cells similar to the endothelial lining of veins.

The whole of the structure of the corpora cavernosa contained within the fibrous sheath consists, therefore, of a sponge-like tissue of areolar spaces freely communicating with each other and filled with venous blood. The spaces may therefore be regarded as large cavernous veins.

The arteries bringing the blood to these spaces are the arteries of the corpora cavernosa and branches from the dorsal artery of the penis, which perforate the fibrous capsule, along the upper surface, especially near the fore part of the organ.

These arteries on entering the cavernous structure divide into branches which are supported and enclosed by the trabeculae. Some of these terminate in a capillary network, the branches of which open directly into the cavernous spaces; others assume a tendril-like appearance, and form convoluted and somewhat dilated vessels, which were named by Müller *helicine arteries*. They project into the spaces, and from them are given off small capillary branches to supply the trabecular structure. They are bound down in the spaces by fine fibrous processes, and are more abundant in the back part of the corpora cavernosa (Fig. 606).

The blood from the cavernous spaces is returned by a series of vessels, some of which emerge in considerable numbers from the base of the glans penis and

FIG. 606.—From the peripheral portion of the corpus cavernosum penis under a low magnifying power. (Copied from Langer.) 1. a. Capillary network. b. Cavernous spaces. 2. Connection of the arterial twig with the cavernous spaces.

converge on the dorsum of the organ to form the dorsal vein; others pass out on the upper surface of the corpora cavernosa and join the dorsal vein; some emerge from the under surface of the corpora cavernosa, and, receiving branches from the corpus spongiosum, wind round the sides of the penis to terminate in the dorsal vein; but the greater number pass out at the root of the penis and join the prostatic plexus.

The **Corpus Spongiosum** encloses the urethra, and is situated in the groove on the under surface of the corpora cavernosa. It commences posteriorly in front of the deep perineal fascia, between the diverging crura of the corpora cavernosa, where it forms a rounded enlargement, the *bulb*, and terminates anteriorly in another expansion, the *glans penis*, which overlaps the anterior rounded extremity of the corpora cavernosa. The central portion, or body of the corpus spongiosum, is cylindrical, and tapers slightly from behind forward.

The *bulb* varies in size in different subjects; it receives a fibrous investment from the anterior layer of the deep perineal fascia, and is surrounded by the Accelerator urinae muscle. The urethra enters the bulb nearer its upper than its lower surface, being surrounded by a layer of erectile tissue, a thin prolongation of which is continued backward round the membranous and prostatic portions of the canal to the neck of the bladder, lying between the two layers of muscular tissue. The portion of the bulb below the urethra presents a partial division into two lobes, being marked externally by a linear raphe, whilst internally there projects inward, for a short distance, a thin fibrous septum, more distinct in early life.

Structure.—The corpus spongiosum consists of a strong fibrous envelope, enclosing a trabecular structure, which contains in its meshes erectile tissue. The fibrous envelope is thinner, whiter in color, and more elastic than that of the corpora cavernosa. The trabeculae are delicate, uniform in size, and the meshes between them small, their long diameter, for the most part, corresponding with that of the penis. The external envelope or outer coat of the corpus spongiosum is formed partly of unstriated muscular fibre, and a layer of the same tissue immediately surrounds the canal of the urethra.

The *lymphatics of the penis* consist of a superficial and deep set; the former are derived from a dense network on the skin of the glans and prepuce and from the mucous membrane of the urethra, and terminate in the superficial inguinal glands; the latter emerge from the corpora cavernosa and corpus spongiosum, and, passing beneath the pubic arch, join the deep lymphatics of the pelvis.

The *nerves* are derived from the internal pudic nerve and the pelvic plexus. On the glans and bulb some filaments of the cutaneous nerves have Pacinian bodies connected with them, and, according to Krause, many of them terminate in a peculiar form of end-bulb.

Surgical Anatomy.—The penis occasionally requires removal for malignant disease. Usually, removal of the ante-scrotal portion is all that is necessary, but sometimes it is requisite to remove the whole organ from its attachment to the rami of the os pubis and ischium. The former operation is performed either by cutting off the whole of the anterior part of the penis with one sweep of the knife, or, what is better, cutting through the corpora cavernosa from the dorsum, and then separating the corpus spongiosum from them, dividing it at a level nearer the glans penis. The mucous membrane of the urethra is then slit up, and the edges of the flap attached to the external skin, in order to prevent contraction of the orifice, which would otherwise take place. The vessels which require ligature are the two dorsal arteries of the penis, the arteries of the corpora cavernosa, and the artery of the septum. When the entire organ requires removal the patient is placed in the lithotomy position, and an incision is made round the root of the penis, and carried down the median line of the scrotum as far as the perineum. The two halves of the scrotum are then separated from each other, and, a catheter having been introduced into the bladder as a guide, the membranous portion of the urethra in front of the triangular ligament is separated from the corpora cavernosa and divided, the catheter having been withdrawn, just behind the bulb. The suspensory ligament is now severed, and the crura separated from the bone with a periosteum scraper, and the whole penis removed. The membranous portion of the urethra, which has not been removed, is now to be attached to the skin at the posterior extremity of the incision in the perineum. The remainder of the wound is to be brought together, free drainage being provided for.

THE TESTES AND THEIR COVERINGS (Fig. 607).

The **Testes** are two small glandular organs which secrete the semen; they are situated in the scrotum, being suspended by the spermatic cords. At an early period of foetal life the testes are contained in the abdominal cavity, behind the peritoneum. Before birth they descend to the inguinal canal, along which they pass with the spermatic cord, and, emerging at the external abdominal ring, they descend into the scrotum, becoming invested in their course by numerous coverings derived from the serous, muscular, and fibrous layers of the abdominal parietes, as well as by the scrotum. The coverings of the testes are—the

Skin	}	Scrotum.
Dartos		
Intercolumnar, or External spermatic fascia.		
Cremasteric fascia.		
Infundibuliform, or Fascia propria (Internal spermatic fascia).		
Tunica vaginalis.		

The **Scrotum** is a cutaneous pouch which contains the testes and part of the spermatic cords. It is divided into two lateral halves by a median line, or *raphe*, which is continued forward to the under surface of the penis and backward along the middle line of the perineum to the anus. Of these two lateral portions, the left is longer than the right, and corresponds with the greater length of the spermatic cord on the left side. Its external aspect varies under different circumstances:

thus, under the influence of warmth and in old and debilitated persons it becomes elongated and flaccid, but under the influence of cold and in the young and robust it is short, corrugated, and closely applied to the testes.

The scrotum consists of two layers, the integument and the dartos.

The **integument** is very thin, of a brownish color, and generally thrown into folds or rugæ. It is provided with sebaceous follicles, the secretion of which has a peculiar odor, and is beset with thinly-scattered, crisp hairs, the roots of which are seen through the skin.

The **dartos** is a thin layer of loose reddish tissue, endowed with contractility: it forms the proper tunic of the scrotum, is continuous, around the base of the scrotum, with the two layers of the superficial fascia of the groin and perineum,

FIG. 607.—Transverse section through the left side of the scrotum and the left testicle. The sac of the tunica vaginalis represented in a distended condition. (Delépine.)

and sends inward a distinct septum, *septum scroti*, which divides it into two cavities for the two testes, the septum extending between the raphe and the under surface of the penis as far as its root.

The dartos is closely united to the skin externally, but connected with the subjacent parts by delicate areolar tissue, upon which it glides with the greatest facility. The dartos is very vascular, and consists of a loose areolar tissue containing unstripped muscular fibre, but no fat. Its contractility is slow, and excited by cold and mechanical stimuli, but not by electricity.

The **intercolumnar fascia** is a thin membrane derived from the margin of the pillars of the external abdominal ring, during the descent of the testes in the fetus, which is prolonged downward around the surface of the cord and testis. It is separated from the dartos by loose areolar tissue, which allows of considerable movement of the latter upon it, but is intimately connected with the succeeding layers.

The **cremasteric fascia** consists of scattered bundles of muscular fibres (*Cremaster muscle*) connected together into a continuous covering by intermediate areolar tissue. The muscular fibres are derived from the lower border of the Internal oblique muscle during the descent of the testis.

The **fascia propria** is a thin membranous layer which loosely invests the surface of the cord. It is a continuation downward of the infundibuliform process of the fascia transversalis and the subperitoneal areolar tissue, and is also acquired during the descent of the testis in the fetus.

The *tunica vaginalis* is described with the proper covering of the testis.

Vessels and Nerves.—The *arteries* supplying the coverings of the testis are: the superficial and deep external pudic, from the femoral; the superficial perineal branch of the internal pudic; and the cremasteric branch from the epigastric. The *veins* follow the course of the corresponding arteries. The *lymphatics* terminate in the inguinal glands. The *nerves* are: the ilio-inguinal branch of the lumbar plexus, the two superficial perineal branches of the internal pudic nerve, the inferior pudendal branch of the small sciatic nerve, and the genital branch of the genito-crural nerve.

The **Spermatic Cord** extends from the internal abdominal ring, where the structures of which it is composed converge, to the back part of the testicle. In the abdominal wall the cord passes obliquely along the inguinal canal, lying at first beneath the Internal oblique, and upon the fascia transversalis; but nearer the pubes it rests upon Poupart's ligament, having the aponeurosis of the External oblique in front of it and the conjoined tendon behind it. It then escapes at the external ring, and descends nearly vertically into the scrotum. The left cord is rather longer than the right, consequently the left testis hangs somewhat lower than its fellow.

Structure of the Spermatic Cord.—The spermatic cord is composed of arteries, veins, lymphatics, nerves, and the excretory duct of the testicle. These structures are connected together by areolar tissue, and invested by the fasciæ brought down by the testicle in its descent.

The *arteries of the cord* are: the spermatic, from the aorta; the artery of the vas deferens, from the superior vesical; and the cremasteric, from the deep epigastric.

The *spermatic artery*, a branch of the abdominal aorta, escapes from the abdomen at the internal or deep abdominal ring, and accompanies the other constituents of the spermatic cord along the inguinal canal and through the external abdominal ring into the scrotum. It then descends to the testicle, and, becoming tortuous, divides into several branches, two or three of which accompany the vas deferens and supply the epididymis, anastomosing with the artery of the vas deferens; others pierce the back of the tunica albuginea and supply the substance of the testis.

The *cremasteric artery* is a branch of the deep epigastric artery. It accompanies the spermatic cord and supplies the Cremaster muscle and other coverings of the cord, anastomosing with the spermatic artery.

The *artery of the vas deferens*, a branch of the superior vesical, is a long slender vessel which accompanies the vas deferens, ramifying upon the coats of that duct, and anastomosing with the spermatic artery near the testis.

The spermatic veins emerge from the back of the testis and receive tributaries from the epididymis; they unite and form a convoluted plexus (*plexus pampiniformis*), which forms the chief mass of the cord: the vessels composing this plexus are very numerous, and ascend along the cord in front of the vas deferens; below the external or superficial abdominal ring they unite to form three or four veins, which pass along the spermatic canal, and, entering the abdomen through the internal or deep abdominal ring, coalesce to form two veins. These again unite to form a single vein, which opens on the right side into the inferior vena cava at an acute angle, and on the left side into the renal vein at a right angle.

The *lymphatic vessels* terminate in the lumbar glands.

The *nerves* are the spermatic plexus from the sympathetic, joined by filaments from the pelvic plexus which accompany the artery of the vas deferens.

Surgical Anatomy.—The scrotum forms an admirable covering for the protection of the testicle. This body, lying suspended and loose in the cavity of the scrotum and surrounded by a serous membrane, is capable of great mobility, and can therefore easily slip about within the scrotum, and thus avoid injuries from blows or squeezes. The skin of the scrotum is very elastic and capable of great distension, and on account of the looseness and amount of subcutaneous tissue the scrotum becomes greatly enlarged in cases of œdema, to which this part is especially liable on account of its dependent position. The scrotum is frequently the seat of

epithelioma: this is no doubt due to the rugæ on its surface, which favor the lodgment of dirt, and this, causing irritation, is the exciting cause of the disease, which is especially common in chimney-sweeps from the lodgment of soot. The scrotum is also the part most frequently affected by elephantiasis.

On account of the looseness of the subcutaneous tissue considerable extravasations of blood may take place from very slight injuries. It is therefore generally recommended never to apply leeches to the scrotum, since they may lead to considerable ecchymosis, but rather to puncture one or more of the superficial veins of the scrotum in cases where local bloodletting from this part is judged to be desirable. The muscular fibre in the dartos causes contraction and considerable diminution in the size of a wound of the scrotum, as after the operation of castration, and is of assistance in keeping the edges together and covering the exposed parts.

THE TESTES.

The **Testes** are suspended in the scrotum by the spermatic cords. As the left spermatic cord is rather longer than the right one, the left testicle hangs somewhat lower than its fellow. Each gland is of an oval form, compressed laterally, and having an oblique position in the scrotum, the upper extremity being directed forward and a little outward, the lower, backward and a little inward; the anterior convex border looks forward and downward; the posterior or straight border, to which the cord is attached, backward and upward.

The anterior and lateral surfaces, as well as both extremities of the organ, are convex, free, smooth, and invested by the tunica vaginalis. The posterior border, to which the cord is attached, receives only a partial investment from that membrane. Lying upon the outer edge of this posterior border is a long, narrow, flattened body, named from its relation to the testis, the epididymis (*ἐπιδυμίς*, testis). It consists of a central portion, or *body*; an upper enlarged extremity, the *globus major*, or head; and a lower pointed extremity, the tail, or *globus minor*. The globus major is intimately connected with the upper end of the testicle by means of its efferent ducts, and the globus minor is connected with its lower end by cellular tissue and a reflection of the tunica vaginalis. The outer surface and upper and lower ends of the epididymis are free and covered by serous membrane; the body is also completely invested by it, excepting along its posterior border. The epididymis is connected to the back of the testis by a fold of the serous membrane. Attached to the upper end of the testis or to the epididymis are one or more small pedunculated bodies. One of them is pretty constantly found between the globus major of the epididymis and the testicle, and is believed to be the remains of the upper extremity of the Müllerian duct (page 138). It is termed the *hydatid of Morgagni*. When the testicle is removed from the body, the position of the vas deferens, on the posterior surface of the testicle and inner side of the epididymis, marks the side to which the gland has belonged.

Size and Weight.—The average dimensions of this gland are from one and a half to two inches in length, one inch in breadth, and an inch and a quarter in the antero-posterior diameter, and the weight varies from six to eight drachms, the left testicle being a little the larger.

The testis is invested by three tunics—the tunica vaginalis, tunica albuginea, and tunica vasculosa.

The **Tunica Vaginalis** is the serous covering of the testis. It is a pouch of serous membrane, derived from the peritoneum during the descent of the testis in the fetus from the abdomen into the scrotum. After its descent that portion of the pouch which extends from the internal ring to near the upper part of the gland becomes obliterated, the lower portion remaining as a shut sac, which invests the outer surface of the testis, and is reflected on to the internal surface of the scrotum; hence it may be described as consisting of a visceral and parietal portion.

The *visceral portion (tunica vaginalis propria)* covers the outer surface of the testis, as well as the epididymis, connecting the latter to the testis by means of a distinct fold. From the posterior border of the gland it is reflected on to the internal surface of the scrotum.

The *parietal portion of the serous membrane (tunica vaginalis reflexa)* is far more extensive than the visceral portion, extending upward for some distance in front and on the inner side of the cord, and reaching below the testis. The inner surface of the tunica vaginalis is free, smooth, and covered by a layer of endothelial cells. The interval between the visceral and parietal layers of this membrane constitutes the cavity of the tunica vaginalis.

The obliterated portion of the pouch may generally be seen as a fibro-cellular thread lying in the loose areolar tissue around the spermatic cord; sometimes this may be traced as a distinct band from the upper end of the inguinal canal, where it is connected with the peritoneum, down to the tunica vaginalis; sometimes it gradually becomes lost on the spermatic cord. Occasionally no trace of it can be detected. In some cases it happens that the pouch of peritoneum does not become obliterated, but the sac of the peritoneum communicates with the tunica vaginalis. This may give rise to one of the varieties of oblique inguinal hernia (page 1073). Or in other cases the pouch may contract, but not become entirely obliterated; it then forms a minute canal leading from the peritoneum to the tunica vaginalis.¹

The **Tunica Albuginea** is the fibrous covering of the testis. It is a dense fibrous membrane, of a bluish-white color, composed of bundles of white fibrous tissue, which interlace in every direction. Its outer surface is covered by the tunica vaginalis, except along its posterior border, at the points of attachment of the epididymis; hence the tunica albuginea is usually considered as a fibro-serous membrane, like the pericardium. This membrane surrounds the glandular structure of the testicle, and at its posterior border is reflected into the interior of the gland, forming an incomplete vertical septum, called the *mediastinum testis* (*corpus Highmorianum*).

The *mediastinum testis* extends from the upper, nearly to the lower, border of the gland, and is wider above than below. From the front and sides of this septum numerous slender fibrous cords and imperfect septa (*trabeculae*) are given off, which radiate toward the surface of the organ, and are attached to the inner surface of the tunica albuginea. They therefore divide the interior of the organ into a number of incomplete spaces, which are somewhat cone-shaped, being broad at their bases at the surface of the gland, and becoming narrower as they converge to the mediastinum. The mediastinum supports the vessels and ducts of the testis in their passage to and from the substance of the gland.

The **Tunica Vasculosa** (*pia mater testis*) is the vascular layer of the testis, consisting of a plexus of blood-vessels held together by a delicate areolar tissue. It covers the inner surface of the tunica albuginea and the different septa in the interior of the gland, and therefore forms an internal investment to all the spaces of which the gland is composed.

Structure.—The glandular structure of the testis consists of numerous lobules (*lobuli testis*). Their number, in a single testis, is estimated by Berres at 250, and by Krause at 400. They differ in size according to their position, those in the middle of the gland being larger and longer. The lobules are conical in shape, the base being directed toward the circumference of the organ, the apex toward the

FIG. 608.—The testis *in situ*, the tunica vaginalis having been laid open.

¹ It is recorded that in the post-mortem examination of Sir Astley Cooper this minute canal was found on both sides of the body. Sir Astley Cooper states that when a student he suffered from inguinal hernia; probably this was of the congenital variety, and the canal found after death was the remains of the one down which the hernia travelled (*Lancet*, vol. ii., 1824, p. 116).

mediastinum. Each lobule is contained in one of the intervals between the fibrous cords and vascular processes which extend between the mediastinum testis and the tunica albuginea, and consists of from one to three or more minute convoluted tubes, the *tubuli seminiferi*. The tubes may be separately unravelled by careful dissection under water, and may be seen to commence either by free caecal ends or by anastomotic loops. The total number of tubes is considered by Munro to be about 300, and the length of each about sixteen feet; by Lauth their number is estimated at 840, and their average length two feet and a quarter. The diameter varies from $\frac{1}{200}$ to $\frac{1}{150}$ of an inch. The tubuli are pale in color in early life, but in old age they acquire a deep yellow tinge from containing much fatty matter. They consist of a membrana propria, inside which are several layers of epithelial cells, the *seminal cells*. The membrana propria is a hyaline structure, consisting of several membranous layers, containing oval flattened nuclei at regular intervals, superimposed on one another. The seminal cells or lining epithelium differ in different tubules. In some tubes they may be seen to consist of an outer layer, next the membrana propria, and two or more layers of inner cells. The former cells are more or less polyhedral in shape, uniform in size, and contain an oval or spherical nucleus; the latter cells, those comprising the inner layers, are spherical and more loosely connected together. The nucleus of most or all of them is in the process of indirect division (*karyokinesis*, page 40), and in consequence of this numerous small spherical daughter-cells are to be seen, lying nearest to the lumen and closely connected together. These small daughter-cells are named *spermatoblasts*, and by a series of changes become converted into spermatozoa. In other tubes the gradual transition of the spermatoblasts into spermatozoa may be traced. In some tubes or parts of tubes the daughter-cells may be seen to have assumed a pear shape, with the pointed end, in which the nucleus is to be found, directed toward the inner seminal cells, while the broad part is directed into the lumen of the tube. In other parts of a tube the broad end may be seen to have become elongated into a rod-shaped body, which constitutes the middle piece of the spermatozoon, while the nucleus forms the head. Again, in other parts of the tubes these young spermatozoa may be seen collected together into fan-shaped groups, and from their distal end—that is to say, the end projecting into the lumen of the tube—a thin long filament, called the tail, is growing out. In the young subject the seminal cells present somewhat the appearance of an epithelial lining, and do not almost fill the tube, as in the adult testis.

The tubules are enclosed in a delicate plexus of capillary vessels, and are held together by an intertubular connective tissue, which presents large interstitial spaces lined by endothelium, which are believed to be the rootlets of lymphatic vessels of the testis.

In the apices of the lobules the tubuli become less convoluted, assume a nearly straight course, and unite together to form from twenty to thirty larger ducts, of about $\frac{1}{50}$ of an inch in diameter, and these, from their straight course, are called *vasa recta*.

The *vasa recta* enter the fibrous tissue of the mediastinum, and pass upward and backward, forming, in their ascent, a close network of anastomosing tubes, which are merely channels in the fibrous stroma, having no proper walls; this constitutes the *rete testis*. At the upper end of the mediastinum the vessels of the rete testis terminate in from twelve to fifteen or twenty ducts, the *vasa efferentia*: they perforate the tunica albuginea, and carry the seminal fluid from the testis to the epididymis. Their course is at first straight; they then become enlarged and exceedingly convoluted, and form a series of conical masses, the *coni vasculosi*, which, together, constitute the globus major of the epididymis. Each cone consists of a single convoluted duct from six to eight inches in length, the diameter of which gradually decreases from the testis to the epididymis. Opposite the bases of the cones the efferent vessels open at narrow intervals into a single duct, which constitutes, by its complex convolutions, the body and globus minor of the epididymis. When the convolutions of this tube are unravelled it

measures upward of twenty feet in length, and increases in breadth and thickness as it approaches the vas deferens. The convolutions are held together by fine areolar tissue and by bands of fibrous tissue.

The vasa recta are of smaller diameter than the seminal tubes, and have very thin parietes. They, as well as the channels of the rete testis, are lined by a single layer of flattened epithelium. The vasa efferentia and the tube of the epididymis have walls of considerable thickness, on account of the presence in them of muscular tissue, which is principally arranged in a circular manner. These tubes are lined by columnar ciliated epithelium.

The **Vas Deferens**, the excretory duct of the testis, is the continuation of the epididymis. Commencing at the lower part of the globus minor, it ascends along the posterior surface of the testis and inner side of the epididymis, and along the back part of the spermatic cord, through the spermatic canal to the internal or deep abdominal ring. From the ring it curves round the outer side of the epigastric artery, crosses the external iliac vessels, and descends into the pelvis at the side of the bladder; it arches backward and downward to its base, crossing over the obliterated hypogastric artery and to the inner side of the ureter. At the base of the bladder it lies between that viscus and the rectum, running along the inner border of the vesicula seminalis. In this situation it becomes enlarged and sacculated, forming the *ampulla*, and then, becoming narrowed at the base of the prostate, unites with the duct of the vesicula seminalis to form the ejaculatory duct. The vas deferens presents a hard and cord-like sensation to the fingers; it is about two feet in length, of cylindrical form, and about a line and a quarter in diameter. Its walls are dense, measuring one-third of a line, and its canal is extremely small, measuring about half a line.

Structure.—The vas deferens consists of three coats: 1. An external or cellular coat. 2. A muscular coat, which in the greater part of the tube consists of two layers of unstriated muscular fibre: an outer, longitudinal in direction, and an inner, circular; but in addition to these, at the commencement of the vas deferens, there is a third layer, consisting of longitudinal fibres, placed internal to the circular stratum, between it and the mucous membrane. 3. An internal or mucous coat, which is pale, and arranged in longitudinal folds; its epithelial covering is of the columnar variety.

A long narrow tube, the *vas aberrans* of *Haller*, is occasionally found connected with the lower part of the canal of the epididymis or with the commencement of the vas deferens. It extends up into the cord for about two or three inches, where it terminates by a blind extremity, which is occasionally bifurcated. Its length varies from an inch and a half to fourteen inches, and sometimes it becomes dilated toward its extremity; more commonly it retains the same diameter throughout. Its structure is similar to that of the vas deferens. Occasionally it is found unconnected with the epididymis.

Surgical Anatomy.—The testicle frequently requires removal for malignant disease: in tuberculous disease, to prevent systemic infection; in cystic disease; in cases of large hernia testis, and in some instances of incompletely descended or misplaced testicle. The operation is a comparatively simple one. An incision is made from the external ring to the bottom of the scrotum into the tunica vaginalis. The coverings are shelled off the organ, and the mesorchium, stretching between the back of the testicle and the scrotum, divided. The cord is then isolated, and an aneurism needle, armed with a double ligature, passed under it, as high as is thought

FIG. 609.—Vertical section of the testicle, to show the arrangement of the ducts.

necessary, and the cord tied in two places, and divided between the ligatures. Sometimes, in cases of malignant disease, it is desirable to open the inguinal canal and tie the cord as near the internal abdominal ring as possible.

VESICULÆ SEMINALES.

The **Seminal Vesicles** are two lobulated membranous pouches placed between the base of the bladder and the rectum, serving as reservoirs for the semen, and secreting a fluid to be added to the secretion of the testicles. Each sac is somewhat pyramidal

FIG. 610.—Base of the bladder, with the vasa deferentia and vesiculæ seminales.

in form, the broad end being directed backward and the narrow end forward toward the prostate. They measure about two and a half inches in length, about five lines in breadth, and two or three lines in thickness. They vary, however, in size, not only in different individuals, but also in the same individual on the two sides. Their *upper surface* is in contact with the base of the bladder, extending from near the termination of the ureters to the base of the prostate gland. Their *under surface* rests upon the rectum, from which they are separated by the recto-vesical fascia. Their *posterior extremities* diverge from each other. Their *anterior extremities* are pointed, and converge toward the base of the prostate gland, where each joins with the corresponding vas deferens to form the ejaculatory duct. Along the inner margin of each vesicula runs the enlarged and convoluted vas deferens. The inner border of the vesiculæ and the corresponding vas deferens form the lateral boundaries of a triangular space, limited behind by the recto-vesical peritoneal fold; the portion of the bladder included in this space rests on the rectum, and corresponds with the trigonum vesicæ in its interior.

Each vesicula consists of a single tube, coiled upon itself and giving off several irregular caecal diverticula, the separate coils, as well as the diverticula, being connected together by fibrous tissue. When uncoiled this tube is about the diameter of a quill, and varies in length from four to six inches; it terminates posteriorly in a *cul-de-sac*; its anterior extremity becomes constricted into a narrow straight duct, which joins on its inner side with the corresponding vas deferens, and forms the ejaculatory duct.

The **ejaculatory ducts**, two in number, one on each side, are formed by the junction of the ducts of the vesiculæ seminales with the vasa deferentia. Each duct is about three-quarters of an inch in length; it commences at the base of the prostate, and runs forward and upward in a canal in its substance, and along the side of the sinus peculiaris, to terminate by a separate slit-like orifice close to or

just within the margins of the sinus. The ducts diminish in size and converge toward their termination.

Structure.—The vesiculæ seminales are composed of three coats: an *external* or *fibro-cellular*; a *middle* or *muscular coat*, which is thinner than in the vas deferens: the muscular fibres are arranged in three layers, consisting of an inner and outer longitudinal stratum and an intermediate layer of circular fibres; and an *internal* or *mucous coat*, which is pale, of a whitish-brown color, and presents a delicate reticular structure, like that seen in the gall-bladder, but the meshes are finer. The epithelium is columnar.

The coats of the ejaculatory ducts are extremely thin. They are: an *outer fibrous layer*, which is almost entirely lost after their entrance into the prostate; a *layer of muscular fibres*, consisting of an outer thin circular and an inner longitudinal layer; and the *mucous membrane*, forming the only constituents of the tubes.

Vessels and Nerves.—The *arteries* supplying the vesiculæ seminales are derived from the middle and inferior vesical and middle hæmorrhoidal. The *veins* and *lymphatics* accompany the arteries. The *nerves* are derived from the pelvic plexus.

Surgical Anatomy.—The vesiculæ seminales are often the seat of an extension of the disease in cases of tuberculous disease of the testicle, and should always be examined from the rectum before coming to a decision with regard to castration in this affection.

Descent of the Testes.

The testes at an early period of foetal life are placed at the back part of the abdominal cavity, behind the peritoneum, in front and a little below the kidneys. The anterior surface and sides are invested by peritoneum. At about the third month of intra-uterine life a peculiar structure, the *gubernaculum testis*, makes its appearance. This structure is at first a slender band which extends from the situation of the internal ring to the epididymis and body of the testicle, and is then continued upward in front of the kidney toward the Diaphragm. As development advances the peritoneum covering the testicle encloses it and forms a mesentery, the *mesorchium*, which also encloses the gubernaculum and forms two folds—one above the testicle, and the other below it. The one above the testicle is the *plica vascularis*, and contains ultimately the spermatic vessels; the one below, the *plica gubernatrix*, contains the lower part of the gubernaculum, which has now grown into a thick cord; it terminates below at the internal ring in a sort of tube, the *processus vaginalis*, which protrudes itself down the inguinal canal. The lower part of the gubernaculum by the fifth month has become a thick cord, whilst the upper part has disappeared. The lower part can now be seen to consist of a central core of unstriped muscle-fibre, and outside this of a firm layer of striped elements, connected, behind the peritoneum, with the abdominal wall. Later on, about the sixth month, the lower end of the gubernaculum can be traced into the inguinal canal, extending to the pubes, and, at a later period, to the bottom of the scrotum. The fold of peritoneum constituting the *processus vaginalis* projects itself downward into the inguinal canal, forming a gradually elongating depression or *cul-de-sac*, which eventually reaches the bottom of the scrotum, and into this the testicle is drawn by the growth of the body of the foetus, for the gubernaculum does not grow commensurately with the growth of other parts, and therefore the testicle, being attached by the gubernaculum to the bottom of the scrotum, is prevented from rising as the body grows, and is drawn first into the inguinal canal, and eventually into the scrotum. By the eighth month the testicle has reached the scrotum, preceded by the lengthened pouch of peritoneum, the *processus vaginalis*, which communicates by its upper extremity with the peritoneal cavity. Just before birth the upper part of the pouch usually becomes closed, and this obliteration extends gradually downward to within a short distance of the testis. The process of peritoneum surrounding the testis, which is

now entirely cut off from the general peritoneal cavity, constitutes the *tunica vaginalis*.¹

In the female, a small cord, corresponding to the gubernaculum in the male, descends to the inguinal region, and ultimately forms the round ligament of the uterus. A pouch of peritoneum accompanies it along the inguinal canal, analogous to the processus vaginalis in the male: it is called the *canal of Nuck*.

Surgical Anatomy.—Abnormalities in the formation and in the descent of the testicle may occur. The testicle may fail to be developed, or the testicle may be fully developed and the vas deferens may be undeveloped in whole or part; or, again, both testicle and vas deferens may be fully developed, but the duct may not become connected to the gland. The testicle may fail in its descent or it may descend into some abnormal position. Thus it may be retained in the position where it was primarily developed, below the kidney; or it may descend to the internal abdominal ring, but fail to pass through this opening; it may be retained in the inguinal canal, which is perhaps the most common position; or it may pass through the external abdominal ring and remain just outside it, failing to pass to the bottom of the scrotum. On the other hand, it may get into some abnormal position: it may pass the scrotum and reach the perineum, or it may fail to enter the inguinal canal, and may find its way through the femoral ring into the crural canal, and present itself on the thigh at the saphenous opening. There is still a third class of cases of abnormality of the testicle, where the organ has descended in due course into the scrotum, but is misplaced. The most common form of this is where the testicle is *inverted*; that is to say, the organ is rotated, so that the epididymis is connected to the front of the scrotum, and the body, surrounded by the tunica vaginalis, is directed backward. In these cases the vas deferens is to be felt in the front of the cord. The condition is of importance in connection with hydrocele and hæmatocoele, and the position of the testicle should always be carefully ascertained before performing any operation for these affections. Again, more rarely, the testicle may be *reversed*. This is a condition in which the top of the testicle, indicated by the globus major of the epididymis, is at the bottom of the scrotum, and the vas deferens comes off from the summit of the organ.

¹ The obliteration of the process of peritoneum which accompanies the cord, and is hence called the *funicular process*, is often incomplete. See section on Inguinal Hernia.

enclosing the common urino-sexual opening. Each labium is formed, externally, of integument covered with hair; internally, of mucous membrane¹ which is continuous with the genito-urinary mucous tract, and, between the two, of a considerable quantity of areolar tissue, fat, and a tissue resembling the dartos of the scrotum, besides vessels, nerves, and glands. The labia are thicker in front, where they form by their meeting the *anterior commissure*. Posteriorly they are not really joined, but appear to become lost in the neighboring integument, terminating close to, and nearly parallel with, each other. Together with the connecting skin between them, they form the posterior commissure or posterior boundary of the vulvar orifice. The interval between the posterior commissure and

FIG. 612.—Vertical median section of the female pelvis.

the anus, about an inch to an inch and a quarter in length, constitutes the perinaeum. The *fourchette* is the anterior edge of the perinaeum, and between it and the hymen is a depression, the *fossa navicularis*. The labia correspond to the scrotum in the male.

The **Labia Minora**, or **Nymphæ**, are two small cutaneous folds, situated within the labia majora, and extending from the clitoris obliquely downward, outward, and backward for about an inch and a half on each side of the orifice of the vagina, between which and the labia majora they are lost. Anteriorly, the two labia minora meet and form the *frænum of the clitoris*. The prepuce of the clitoris, passing backward on each side, is inserted, as it were, into the labia, but is not actually a part of them. The nymphæ are really modified skin. Their internal surfaces have numerous sebaceous follicles.

The **Clitoris** is an erectile structure analogous to the corpora cavernosa of the

¹ The term mucous membrane is used here in its broad sense to denote an internal surface kept continuously moist by secretion, and communicating directly or indirectly with the external air.

penis. It is situated beneath the anterior commissure, partially hidden between the anterior extremities of the labia minora. It is connected to the rami of the os pubis and ischium on each side by a crus; the body is short and concealed beneath the labia; the free extremity, or *glans clitoridis*, is a small rounded tubercle, consisting of spongy erectile tissue, and highly sensitive. It is provided, like the penis, with a suspensory ligament, and with two small muscles, the *Erectores clitoridis*, which are inserted into the crura of the clitoris. The clitoris consists of two corpora cavernosa, composed of erectile tissue enclosed in a dense layer of fibrous membrane, united together along their inner surfaces by an incomplete fibrous pectiniform septum.

Between the clitoris and the entrance of the vagina is a triangular smooth surface, bounded on each side by the nymphæ; this is the *vestibule*.

The orifice of the urethra (*meatus urinarius*) is situated at the back part of the vestibule, about an inch below the clitoris and near the margin of the vagina, surrounded by a prominent elevation of the mucous membrane. Below the *meatus urinarius* is the orifice of the vagina, more or less closed in the virgin by a membranous fold, the *hymen*.

The *Hymen* is a membranous fold which closes to a greater or less extent the opening of the vagina. It varies much in shape. Its commonest form is that of a ring, generally broadest posteriorly: sometimes it is represented by a semilunar fold, with its concave margin turned toward the pubes. A complete septum stretched across the lower part of the vaginal orifice is called "imperforate hymen." Occasionally it is cribriform, or its free margin forms a membranous fringe, or it may be entirely absent. It may persist after copulation, so that it cannot be considered as a test of virginity. After parturition the small rounded elevations known as the *carunculae myrtiformes* are found as the remains of the hymen.

Glands of Bartholin.—On each side of the commencement of the vagina, and behind the hymen, is a round or oblong body, of a reddish-yellow color, and of the size of a horse-bean, analogous to Cowper's gland in the male. It is called the *gland of Bartholin*. Each gland opens by means of a long single duct on each side external to the hymen.

Bulbi Vestibuli.—Extending from the clitoris, along either side of the vestibule, and lying a little behind the nymphæ, are two large oblong masses, about an inch in length, consisting of a plexus of veins enclosed in a thin layer of fibrous membrane. These bodies are narrow in front, rounded below, and are connected with the crura of the clitoris and rami of the pubes: they are termed by Kobelt the *bulbi vestibuli*, and he considers them analogous to the bulb of the corpus spongiosum in the male. Immediately in front of these bodies is a smaller venous plexus, continuous with the bulbi vestibuli behind and the glans clitoridis in front: it is called by Kobelt the *pars intermedia*, and is considered by him as analogous to that part of the body of the corpus spongiosum which immediately succeeds the bulb.

RELATIONS OF THE BLADDER.

The *Bladder* is situated at the anterior part of the pelvis. It is in relation, *in front*, with the symphysis pubis; *behind*, with the utero-vesical pouch of peritoneum, which separates it from the body of the uterus; its *base* lies in contact with the connective tissue in front of the cervix and upper part of the vagina. *Laterally*, is the recto-vesical fascia. The bladder is said by some anatomists to be larger in the female than in the male. At any rate, it does not rise above the symphysis pubis till more distended than in the male, but this is perhaps owing to the more capacious pelvis rather than to its being of actually larger size.

THE URETHRA.

The *Urethra* is a narrow membranous canal, about an inch and a half in length, extending from the neck of the bladder to the *meatus urinarius*. It is placed beneath the symphysis pubis, imbedded in the anterior wall of the vagina.

and its direction is obliquely downward and forward, its course being slightly curved, the concavity directed forward and upward. Its diameter when undilated is about a quarter of an inch. The urethra perforates the triangular ligament precisely as in the male.

Structure.—The urethra consists of three coats: muscular, erectile, and mucous.

The *muscular coat* is continuous with that of the bladder; it extends the whole length of the tube, and consists of a circular stratum of muscular fibres. In addition to this, between the two layers of the triangular ligament, the female urethra is surrounded by the Compressor urethræ, as in the male.

A *thin layer of spongy erectile tissue*, containing a plexus of large veins intermixed with bundles of unstriped muscular fibre, lies immediately beneath the mucous coat.

The *mucous coat* is pale, continuous externally with that of the vulva, and internally with that of the bladder. It is thrown into longitudinal folds, one of which, placed along the floor of the canal, resembles the verumontanum in the male urethra. It is lined by laminated epithelium, which becomes transitional near the bladder. Its external orifice is surrounded by a few mucous follicles.

The urethra, from not being surrounded by dense resisting structures, as in the male, admits of considerable dilatation, which enables the surgeon to remove with considerable facility calculi or other foreign bodies from the cavity of the bladder.

THE RECTUM.

The **Rectum** is more capacious and less curved in the female than in the male.

The *first portion* extends from the left sacro-iliac symphysis to the middle of the sacrum. Its connections are similar to those in the male.

The *second portion* extends to the tip of the coccyx. It is covered in front by the peritoneum for a short distance, at its upper part: it is in relation with the posterior wall of the vagina.

The *third portion* curves backward from the vagina to the anus, leaving a space which corresponds on the surface of the body to the perineum. Its extremity is surrounded by the Sphincter muscles, and its sides are supported by the Levatores ani.

INTERNAL ORGANS.

The **Internal Organs of Generation** are—the vagina, the uterus and its appendages, the Fallopian tubes, the ovaries and their ligaments, and the round ligaments.

The **Vagina** extends from the vulva to the uterus. It is situated in the cavity of the pelvis, behind the bladder and in front of the rectum. Its direction is curved upward and backward, at first in the line of the outlet, and afterward in that of the axis of the cavity of the pelvis. Its walls are ordinarily in contact, and its usual shape on transverse section is that of an **H**, the transverse limb being slightly curved forward or backward, whilst the lateral limbs are somewhat convex toward the median line. Its length is about two inches along its anterior wall, and two and three-quarter inches along its posterior wall. It is constricted at its commencement, and becomes dilated medially, and narrowed near its uterine extremity; it surrounds the vaginal portion of the cervix uteri, a short distance from the os, its attachment extending higher up on the posterior than on the anterior wall of the uterus.

Relations.—Its *anterior surface* is in relation with the base of the bladder and with the urethra. Its *posterior surface* is connected for the lower three-fourths of its extent to the anterior wall of the rectum, the upper fifth being separated from that tube by the recto-vaginal fold of peritoneum, which forms a *cul-de-sac* between the vagina and rectum. Its sides give attachment superiorly to the broad ligaments, and inferiorly to the Levatores ani muscles and recto-vesical fascia.

Structure.—The vagina consists of an internal mucous lining, of a muscular coat, and between the two of a layer of erectile tissue.

The *mucous membrane*¹ is continuous above with that lining the uterus. Its inner surface presents, along the anterior and posterior walls, a longitudinal ridge or raphe, called the *columns of the vagina*, and numerous transverse ridges or rugæ, extending outward from the raphe on either side. These rugæ are divided by furrows of variable depth, giving to the mucous membrane the appearance of being studded over with conical projections or papillæ; they are most numerous near the orifice of the vagina, especially in females before parturition. The epithelium covering the mucous membrane is of the squamous variety. The submucous tissue is very loose, and contains numerous large veins, which by their anastomoses form a plexus, together with smooth muscular fibres derived from the muscular coat; it is regarded by Gussenbauer as an erectile tissue. It contains a number of mucous crypts, but no true glands.

The *muscular coat* consists of two layers: an external longitudinal, which is far the stronger, and an internal circular layer. The longitudinal fibres are continuous with the superficial muscular fibres of the uterus. The strongest fasciculi are those attached to the recto-vesical fascia on each side. The two layers are not distinctly separable from each other, but are connected by oblique decussating fasciculi which pass from the one layer to the other. In addition to this the vagina at its lower end is surrounded by a band of striped muscular fibres, the *sphincter vaginae* (see page 466).

External to the muscular coat is a layer of connective tissue containing a large plexus of blood-vessels.

The *erectile tissue* consists of a layer of loose connective tissue situated between the mucous membrane and the muscular coat; imbedded in it is a plexus of large veins, and numerous bundles of unstriped muscular fibres derived from the circular muscular layer. The arrangement of the veins is similar to that found in other erectile tissues.

THE UTERUS.

The **Uterus** is the organ of gestation, receiving the fecundated ovum in its cavity, retaining and supporting it during the development of the fœtus, and becoming the principal agent in its expulsion at the time of parturition.

In the *virgin state* it is pear-shaped, flattened from before backward, and situated in the cavity of the pelvis between the bladder and the rectum; it is retained in its position by the round and broad ligaments on each side, and projects into the upper end of the vagina below. Its upper end, or base, is directed upward and forward; its lower end, or apex, downward and backward, in the line of the axis of the inlet of the pelvis. It therefore forms an angle with the vagina, since the direction of the vagina corresponds to the axis of the cavity and outlet of the pelvis. The uterus measures about three inches in length, two in breadth at its upper part, and nearly an inch in thickness, and it weighs from an ounce to an ounce and a half.

It consists of two parts: (1) the *body*, with its upper broad extremity, the *fundus*; and (2) the *cervix*, or *neck*, which is partly above the vagina and partly in the vagina. The fundus is placed on a line below the level of the brim of the pelvis, being directed forward behind the upper portion of the anterior pelvic wall.

The division between the body and cervix is indicated externally by a slight constriction, and by the reflection of the peritoneum from the anterior surface of the uterus on to the bladder, and internally by a narrowing of the canal, called the *internal os*.

The *body* gradually narrows from the fundus to the neck. Its anterior surface is flattened, covered by peritoneum in the upper three-fourths of its extent, and separated from the bladder by the utero-vesical pouch. Its *posterior surface* is convex transversely, covered by peritoneum throughout, and separated from the rectum by some convolutions of the intestine. Its *lateral margins* are concave, and

¹ See foot-note, page 1048.

give attachment to the Fallopian tube above, the round ligament below and in front of this, and the ligament of the ovary behind and between both of these structures.

The *cervix* is the lower constricted segment of the uterus; around its circumference is attached the upper end of the vagina, which extends upward a greater distance behind than in front.

The supravaginal portion is not covered by peritoneum in front; a pad of cellular tissue is interposed between it and the bladder. Behind, the peritoneum is extended over it. The vaginal portion is the rounded lower end projecting into the vagina. On its surface is a small aperture, the *os uteri*, generally circular in shape, but sometimes oval or almost linear. The margin of the opening is, in the absence of past parturition or disease, quite smooth.

Ligaments.—The ligaments of the uterus are eight in number: one anterior;

FIG. 613.—Douglas's pouch. (From a preparation in the Museum of the Royal College of Surgeons.)

one posterior; two lateral or broad; two sacro-uterine,—all these being formed of peritoneum—and, lastly, two round ligaments.

The *anterior ligament* (vesico-uterine) is reflected on to the bladder from the front of the uterus, at the junction of the supravaginal cervix and body.

The *posterior ligament* (recto-uterine) passes from the posterior wall of the uterus over the upper fifth of the vagina, and thence on to the rectum and sacrum. It thus forms a pouch called *Douglas's pouch* (Fig. 613), the boundaries of which are, in front, the posterior wall of the uterus, the supravaginal cervix, and the upper fifth of the vagina; behind, the rectum and sacrum; above, the small intestine; and, laterally, the sacro-uterine ligaments.

The *two lateral or broad ligaments* pass from the sides of the uterus to the lateral walls of the pelvis, forming a septum across the pelvis, which divides that cavity into two portions. In the anterior part are contained the bladder,

urethra, and vagina; in the posterior part, the rectum. Between the two layers of each broad ligament are contained—(1) the Fallopian tubes superiorly; (2) the round ligament; (3) the ovary and its ligament; (4) the parovarium, or organ of Rosenmüller; (5) connective tissue; and (6) unstriped muscular fibre. Between the fimbriated extremity of the tube and the lower attachment of the broad ligament is a concave rounded margin called the *infundibulo-pelvic ligament* (Fig. 616).

The *sacro-uterine ligaments* pass from the second and third bones of the sacrum, downward and forward, to be attached one on each side of the uterus at the junction of the supravaginal cervix and the body, this point corresponding internally to the position of the os internum.

The *cavity of the uterus* is small in comparison with the size of the organ:

FIG. 614.—Side view of the female pelvic organs. (From a preparation in the Museum of the Royal College of Surgeons.)

that portion of the cavity which corresponds to the body is triangular, flattened from before backward, so that its walls are closely approximated, and having its base directed upward toward the fundus. At each superior angle is a funnel-shaped cavity, which constitutes the remains of the division of the body of the uterus into two cornua, and at the bottom of each cavity is the minute orifice of the Fallopian tube. At the inferior angle of the uterine cavity is a small constricted opening, the internal orifice (*ostium internum*), which leads into the cavity of the cervix.

The *cavity of the cervix* is somewhat fusiform, flattened from before backward, broader at the middle than at either extremity, and communicates below with the vagina. The wall of the canal presents, anteriorly and posteriorly, a longitudinal column, from which proceed a number of small oblique columns, giving the appearance of branches from the stem of a tree; and hence the name *arbor vite uterina* applied to it. These folds usually become very indistinct after the first labor.

Structure.—The uterus is composed of three coats—an external serous coat, a middle or muscular, and an internal mucous coat.

The *serous coat* is derived from the peritoneum; it invests the fundus and the whole of the posterior surface of the body of the uterus, but only the upper three-fourths of its anterior surface. In the lower fourth of the posterior surface the peritoneum, though covering the uterus, is not closely connected with it, being separated from it by a layer of loose cellular tissue and some large veins.

The *muscular coat* forms the chief bulk of the substance of the uterus. In the unimpregnated state it is dense, firm, of a grayish color, and cuts almost like cartilage. It is thick opposite the middle of the body and fundus, and thin at the orifices of the Fallopian tubes. It consists of bundles of unstriped muscular fibres, disposed in layers, intermixed with areolar tissue, blood-vessels, lymphatic vessels, and nerves. In the impregnated state the muscular tissue becomes more prominently developed, and is disposed in three layers—external, middle, and internal.

The external layer is placed beneath the peritoneum, disposed as a thin plane on the anterior and posterior surfaces. It consists of fibres which pass transversely across the fundus, and, converging at each superior angle of the uterus, are continued on the Fallopian tube, the round ligament, the ligament of the ovary: some passing at each side into the broad ligament, and others running backward from the cervix into the recto-uterine ligaments.

The middle layer of fibres, which is thickest, presents no regularity in its arrangement, being disposed longitudinally, obliquely, and transversely. It contains most blood-vessels.

The internal or deep layer consists of circular fibres arranged in the form of two hollow cones, the apices of which surround the orifices of the Fallopian tubes, their bases intermingling with one another on the middle of the body of the uterus. At the internal os these circular fibres form a distinct sphincter.

The *mucous membrane* is thin, smooth, and closely adherent to the subjacent tissue. It is continuous, through the fimbriated extremity of the Fallopian tubes, with the peritoneum, and through the os uteri with the lining of the vagina.

In the body of the uterus it is smooth, soft, of a pale red color, lined by columnar ciliated epithelium, and presents, when viewed with a lens, the orifices of numerous tubular follicles arranged perpendicularly to the surface. It is unprovided with any submucosa, but is intimately connected with the innermost layer of the muscular coat, which by some anatomists is regarded as the *muscularis mucosæ*. In structure it differs from ordinary mucous membrane, consisting of an embryonic nucleated and highly cellular form of connective tissue in which run numerous large lymphatics. In it are the tube-like *uterine glands*, which are of small size in the unimpregnated uterus, but shortly after impregnation become enlarged, elongated, presenting a contorted or waved appearance toward their closed extremities, which reaches into the muscularis, and may be single or bifid. They consist of a delicate membrane, lined by an epithelium, which becomes ciliated toward the orifices. In the impregnated uterus the epithelium loses its ciliated character, is thicker and tougher, and is provided with a submucous layer of areolar tissue. In the cervix the mucous membrane is sharply differentiated from that of the uterine cavity. It is thrown into numerous transverse folds, which are arranged along an anterior and posterior longitudinal raphe, presenting an appearance which has received the name of *arbor vitæ*. In the upper two-thirds of the canal the mucous membrane is provided with numerous deep glandular follicles, which secrete a clear viscid alkaline mucus; and in addition, extending through the whole length of the canal, are a variable number of little cysts, presumably follicles, which have become occluded and distended with retained secretion. They are called the *ovula Nabothi*. The mucous membrane covering the lower half of the cervical canal presents numerous papillæ. The epithelium of the upper two-thirds is cylindrical and ciliated, but below this it loses its cilia, and gradually changes to squamous epithelium close to the external os.

Vessels and Nerves.—The *arteries of the uterus* are the uterine, from the internal iliac, and the ovarian, from the aorta. They are remarkable for their tortuous course in the substance of the organ and for their frequent anastomoses. The termination of the ovarian artery meets the termination of the uterine artery, and forms an anastomotic trunk from which branches are given off to supply the uterus, their disposition being, as shown by John Williams, circular. The *veins* are of large size, and correspond with the arteries. In the impregnated uterus these vessels are termed the *uterine sinuses*, consisting of the lining membrane of the veins adhering to the walls of the canal channelled through the substance of the uterus. They terminate in the uterine plexuses. The *lymphatics* of the body terminate in the lumbar glands, those of the cervix in the pelvic glands. The

FIG. 615.—The arteries of the internal organs of generation of the female, seen from behind. (After Hyrtl.)

nerves are derived from the inferior hypogastric and ovarian plexuses, and from the third and fourth sacral nerves.

The form, size, and situation of the uterus vary at different periods of life and under different circumstances.

In the fetus the uterus is contained in the abdominal cavity, projecting beyond the brim of the pelvis. The cervix is considerably larger than the body.

At puberty the uterus is pyriform in shape, and weighs from eight to ten drachms. It has descended into the pelvis, the fundus being just below the level of the brim of this cavity. The arbor vitæ is distinct, and extends to the upper part of the cavity of the organ.

During menstruation the organ is enlarged, and more vascular, its surfaces rounder; the os externum is rounded, its labia swollen, and the lining membrane of the body thickened, softer and of a darker color. According to J. Williams, at each recurrence of menstruation a molecular disintegration of the mucous membrane takes place, which leads to its complete removal, only the bases of the glands imbedded in the muscle being left. At the cessation of menstruation by a proliferation of the remaining structures a fresh mucous membrane is formed.

During pregnancy the uterus becomes enormously enlarged, and in the ninth month reaches the epigastric region. The increase in size is partly due to growth of pre-existing muscle and partly to development of new fibres.

After parturition the uterus nearly regains its usual size, weighing about an ounce and a half; but its cavity is larger than in the virgin state, the external orifice is more marked, its edges present a fissured surface, its vessels are tortuous, and its muscular layers are more defined.

In old age the uterus becomes atrophied, and paler and denser in texture; a more distinct constriction separates the body and cervix. The ostium internum and, occasionally, the vaginal orifice often become obliterated, and its labia almost entirely disappear.

APPENDAGES OF THE UTERUS.

The **appendages of the uterus** are the Fallopian tubes, the ovaries and their ligaments, and the round ligaments. They are placed in the following order: in front is the round ligament; the Fallopian tube occupies the upper margin of the broad ligament; the ovary and its ligament are behind and below both.

THE FALLOPIAN TUBES.

The **Fallopian Tubes**, or **Oviducts**, convey the ova from the ovaries to the cavity of the uterus. They are two in number, one on each side, situated in the upper margin of the broad ligament, extending from each superior angle of the uterus to the sides of the pelvis. Each tube is about four inches in length; and is described as consisting of three portions: (1) the *isthmus*, or inner constricted half; (2) the *ampulla*, or outer dilated portion, which curves over the ovary; and (3) the

FIG. 616.—Uterine appendages, seen from behind. (Henle.)

infundibulum with its *ostium abdominale*, surrounded by fimbriae, one of which is attached to the ovary, the *fimbria ovarica*. The general direction of the Fallopian tube is outward, backward, and downward. The uterine opening is minute, and will only admit a fine bristle; the abdominal opening is comparatively much larger. In connection with the fimbriae of the Fallopian tube or with the broad ligament close to them there is frequently one or more small vesicles floating on a long stalk of peritoneum. These are termed the *hydatis of Morgagni*, and are probably the remains of the terminal sacs of the Müllerian ducts.

Structure.—The Fallopian tube consists of three coats—serous, muscular, and mucous.

The *external* or *serous coat* is peritoneal.

The *middle* or *muscular coat* consists of an external longitudinal and an internal circular layer of muscular fibres continuous with those of the uterus.

The *internal* or *mucous coat* is continuous with the mucous lining of the uterus and, at the free extremity of the tube, with the peritoneum. It is thrown into longitudinal folds, which in the outer, larger part of the tube, or ampulla, are much more extensive than in the narrow canal of the isthmus. The lining epithelium is columnar ciliated. This form of epithelium is also found on the inner surface of the fimbriae, while on the outer or serous surfaces of these processes the epithelium gradually merges into the endothelium of the peritoneum.

THE OVARIES.

The **Ovaries** (*testes muliebres*, Galen) are analogous to the testes in the male. They are oval-shaped bodies of an elongated form, flattened from above downward, situated one on each side of the uterus, in the posterior part of the broad ligament behind and below the Fallopian tubes. Each ovary is connected by its anterior straight margin to the broad ligaments; by its inner extremity to the uterus by a proper ligament, the *ligament of the ovary*; and by its outer end to the fimbriated extremity of the Fallopian tube by the ovarian fimbria; its superior and inferior surfaces and posterior convex border are free. The ovaries are of a grayish-pink color, and present either a smooth or puckered, uneven surface. They are each about an inch and a half in length, three-quarters of an inch in width, and about a third of an inch thick, and weigh from one to two drachms.

The exact position of the ovary has been the subject of considerable difference of opinion, and writers differ much as to what is to be regarded as the normal position. The fact appears to be that it is differently placed in different individuals. Hasse has described it as being situated with its long axis transverse, or almost transverse, to the pelvic cavity. Schultze, on the other hand, believes that its

FIG. 617.—The uterus and its appendages. Posterior view. The parts have been somewhat displaced from their proper position in the preparation of the specimen; thus the right ovary has been raised above the Fallopian tube, and the fimbriated extremities of the tubes have been turned upward and outward. (From a preparation in the Royal College of Surgeons.)

long axis is antero-posterior. Kölliker asserts that the truth lies between these two views, and that the ovary is placed obliquely in the pelvis, its long axis lying parallel to the external iliac vessels, with its surface directed inward and outward, and its convex free border upward. His has made some important observations on this subject, and his views are largely accepted. He teaches that the uterus rarely lies symmetrically in the middle of the pelvic cavity, but is generally inclined to one or other side, most frequently to the left, in the proportion of three to two. The position of the two ovaries varies according to the inclination of the uterus. When the uterus is inclined to the left, the ovary of this side lies with its long axis vertical and with one side closely applied to the outer wall of the pelvis, while the ovary of the opposite side, being dragged upon by the inclination of the uterus, lies obliquely, its outer extremity being retained in close apposition to the side of the pelvis by the infundibulo-pelvic ligament (page 1053). When, on the other hand, the uterus is inclined to the right, the position of the two ovaries is exactly reversed, the right being vertical and the left oblique. In whichever position the ovary is placed, the Fallopian tube forms a loop around it, the uterine half ascending obliquely over it, and the outer half, including the dilated extremity, descending and bulging freely behind it. From this extremity the fimbriae pass upward on to the ovary and closely embrace it.

Structure.—The ovary consists of a number of Graafian vesicles imbedded in

the meshes of a stroma or framework, and invested by a serous covering derived from the peritoneum.

Serous Covering.—Though the investing membrane of the ovary is derived from the peritoneum, it differs essentially from that structure, inasmuch as its epithelium consists of a single layer of columnar cells, instead of the flattened endothelial cells of other parts of the membrane; this has been termed the *germinal epithelium of Waldeyer*, and gives to the surface of the ovary a dull gray aspect instead of the shining smoothness of serous membranes generally.

Stroma.—The stroma is a peculiar soft tissue, abundantly supplied with blood-vessels, consisting for the most part of spindle-shaped cells, with a small amount of ordinary connective tissue. These cells have been regarded by some anatomists as unstriated muscle-cells, which, indeed, they most resemble (His); by others as connective-tissue cells (Waldeyer, Henle, and Kölliker). On the surface of the organ this tissue is much condensed, and forms a layer composed of short connective-tissue fibres, with fusiform cells between them. This was formerly regarded as a distinct fibrous covering, and was termed the *tunica albuginea*, but is nothing more than a condensed layer of the stroma of the ovary.

Graafian Vesicles.—Upon making a section of an ovary numerous round transparent vesicles of various sizes are to be seen; they are the *Graafian vesicles*, the ovisacs containing the ova. Immediately beneath the superficial covering is a layer of stroma, in which are a large number of minute vesicles, of uniform size, about $\frac{1}{100}$ of an inch in diameter. These are the Graafian vesicles in their earliest condition, and the layer where they are found has been termed the *cortical layer*.

They are especially numerous in the ovary of the young child. After puberty and during the whole of the child-bearing period large and mature, or almost mature, Graafian vesicles are also found in the cortical layer in small numbers, and also "corpora lutea," the remains of vesicles which have burst and are

FIG. 618.—Section of the ovary. (After Schron.) 1. Outer covering. 1'. Attached border. 2. Central stroma. 3. Peripheral stroma. 4. Blood-vessels. 5. Graafian follicles in their earliest stage. 6, 7, 8. More advanced follicles. 9. An almost mature follicle. 9'. Follicle from which the ovum has escaped. 10. Corpus luteum.

FIG. 619.—Section of the Graafian vesicle. (After Von Baer.)

undergoing atrophy and absorption. Beneath this superficial stratum other large and more mature Graafian vesicles are found imbedded in the ovarian stroma. These increase in size as they recede from the surface toward a highly vascular stroma in the centre of the organ, termed the *medullary substance (zona vasculosa, Waldeyer)*. This stroma forms the tissue of the hilum by which the ovary is attached, and through which the blood-vessels enter; it does not contain any Graafian vesicles.

The *Graafian vesicles* consist of an external fibro-vascular coat connected with the surrounding stroma of the ovary by a network of blood-vessels; and an internal coat, named *ovicapsule*, which is lined by a layer of nucleated cells, called the *membrana granulosa*. The fluid contained in the interior of the vesicles is transparent and albuminous, and in it is suspended the ovum. In that part of the mature Graafian vesicle which is nearest the surface of the ovary the cells of the *membrana granulosa* are collected into a mass which projects into the cavity

of the vesicle. This is termed the *discus proligerus*, and in this the ovum is imbedded.¹

The ova are formed from the germ-epithelium on the surface of the ovary: the cells become enlarged and involuted, forming little depressions on the surface of the ovary. As they sink deeper into the tissue they become enclosed by the outgrowth of processes from the stroma of the ovary, and, becoming surrounded, their connection with the surface is cut off, and the germ-epithelium forming the involution is contained in a cavity, the future Graafian follicle. The germ-cell or cells now form the ovum; the cell-wall forms the vitelline membrane; the nucleus, the germinal area; and a nucleolus, which soon appears, the germinal spot. A clear homogeneous protoplasm is formed within the cell, constituting the yolk, and thus the primordial ovum is developed. According to Dr. Foullis, the cells of the *membrana granulosa* are formed out of the nuclei of the fibro-cellular stroma of the ovary.²

The development and maturation of the Graafian vesicles and ova continue uninterruptedly from puberty to the end of the fruitful period of woman's life, while their formation commences before birth. Before puberty the ovaries are small, the Graafian vessels contained in them are disposed in a comparatively thick layer in the cortical substance; here they present the appearance of a large number of minute closed vesicles, constituting the early condition of the Graafian vesicle; many, however, never attain full development, but shrink and disappear, their ova being incapable of impregnation. At puberty the ovaries enlarge, are more vascular, the Graafian vesicles are developed in greater abundance, and their ova are capable of fecundation.

Discharge of the Ovum.—The Graafian vesicles, after gradually approaching the surface of the ovary, burst: the ovum and fluid contents of the vesicles are liberated, and escape on the exterior of the ovary, passing thence into the Fallopian tube.³

In the fœtus the ovaries are situated, like the testes, in the lumbar region, near the kidneys. They may be distinguished from those bodies at an early period by their elongated and flattened form, and by their position, which is at first oblique and then nearly transverse. They gradually descend into the pelvis.

Lying above the ovary in the broad ligament between it and the Fallopian tube is the *organ of Rosenmüller*, called also the *parovarium* or *epoöphoron*. This is the remnant of a fœtal structure, the development of which has been described at a former page (page 139). In the adult it consists of a few closed convoluted tubes lined with epithelium, some of them atrophied, and one, usually distinguishable from the rest, ends in a bulbous or hydatid swelling. The parovarium is connected at its uterine extremity with the remains of the Wolffian duct—the duct of Gartner.

The **Ligament of the Ovary** is a rounded cord which extends from each superior angle of the uterus to the inner extremity of the ovary; it consists of fibrous tissue and a few muscular fibres derived from the uterus.

The **Round Ligaments** are two rounded cords, between four and five inches in length, situated between the layers of the broad ligament in front of and below the Fallopian tube. Commencing on each side at the superior angle of the uterus, this ligament passes forward, upward, and outward through the internal abdominal ring, along the inguinal canal, to the labia majora, in which it becomes lost. The round ligament consists principally of muscular tissue prolonged from the uterus; also of some fibrous and areolar tissue, besides blood-vessels and nerves, enclosed in a duplicature of peritoneum, which in the fœtus is prolonged in the form of a tubular process for a short distance into the inguinal canal. This process is called the *canal of Nuck*. It is generally obliterated in the adult, but sometimes remains

¹ For a description of the ovum, see page 100.

² *Proceedings of the Royal Society of Edinburgh*, April, 1875.

³ This is effected either by application of the tube to the ovary, or by a curling upward of the fimbriated extremity, so that the ovum is caught as it falls.

pervious even in advanced life. It is analogous to the peritoneal pouch which accompanies the descent of the testis.

Vessels and Nerves.—The *arteries of the ovaries and Fallopian tubes* are the ovarian from the aorta. They enter the attached border, or hilum, of the ovary. The *veins* follow the course of the arteries; they form a plexus near the ovary, the *pampiniform plexus*. The *nerves* are derived from the inferior hypogastric or pelvic plexus, and from the ovarian plexus, the Fallopian tube receiving a branch from one of the uterine nerves.

THE MAMMARY GLANDS.

The **mammæ**, or breasts, are accessory glands of the generative system, which secrete the milk. They exist in the male as well as in the female, but in the former only in the rudimentary state, unless their growth is excited by peculiar circumstances. In the female they are two large hemispherical eminences situated

FIG. 620.—Dissection of the lower half of the female breast during the period of lactation. (From Luschka.)

toward the lateral aspect of the pectoral region, corresponding to the intervals between the third and sixth or seventh ribs, and extending from the side of the sternum to the axilla. Their weight and dimensions differ at different periods of life and in different individuals. Before puberty they are of small size, but enlarge as the generative organs become more completely developed. They increase during pregnancy, and especially after delivery, and become atrophied in old age. The left mamma is generally a little larger than the right. Their base is nearly circular, flattened or slightly concave, and has its long diameter directed upward and outward toward the axilla; they are separated from the Pectoral muscles by a thin layer of superficial fascia. The outer surface of the mamma is convex, and presents, just below the centre, a small conical prominence, the nipple (*mammilla*). The surface of the nipple is dark-colored and surrounded by an areola having a colored tint. In the virgin the areola is of a delicate rosy hue; about the second month after impregnation it enlarges and acquires a darker tinge, which increases as pregnancy advances, becoming in some cases of a dark-brown or even black color. This color diminishes as soon as lactation is over, but is never entirely lost throughout life. These changes in the color of the areola are of importance in forming a conclusion in a case of suspected first pregnancy.

The **nipple** is a cylindrical or conical eminence capable of undergoing a sort of erection from mechanical excitement, a change mainly due to the contraction of its muscular fibres. It is of a pink or brownish hue, its surface wrinkled and provided with papillæ, and it is perforated by numerous orifices, the apertures of the lactiferous ducts. Near the base of the nipple and upon the surface of the areola are numerous sebaceous glands, which become much enlarged during lactation, and present the appearance of small tubercles beneath the skin. These glands secrete a peculiar fatty substance which serves as a protection to the integument of the nipple during the act of sucking. The nipple consists of numerous vessels, intermixed with plain muscular fibres, which are principally arranged in a circular manner around the base, some few fibres radiating from base to apex.

Structure.—The mamma consists of gland-tissue; of fibrous tissue, connecting its lobes; and of fatty tissue in the intervals between the lobes. The gland-tissue, when freed from fibrous tissue and fat, is of a pale reddish color, firm in texture, circular in form, flattened from before backward, thicker in the centre than at the circumference, and presenting several inequalities on its surface, especially in front. It consists of numerous lobes, and these are composed of lobules connected together by areolar tissue, blood-vessels, and ducts. The smallest lobules consist of a cluster of rounded vesicles, which open into the smallest branches of the lactiferous ducts: these ducts, uniting, form larger ducts, which terminate in a single canal, corresponding with one of the chief subdivisions of the gland. The number of excretory ducts varies from fifteen to twenty: they are termed the *tubuli lactiferi*, or *galactophori*. They converge toward the areola, beneath which they form dilatations, or *ampullæ*, which serve as reservoirs for the milk, and at the base of the nipple become contracted and pursue a straight course to its summit, perforating it by separate orifices considerably narrower than the ducts themselves. The ducts are composed of areolar tissue, with longitudinal and transverse elastic fibres and longitudinal muscular fibres: their mucous lining is continuous, at the point of the nipple, with the integument. The epithelium of the mammary gland differs according to the state of activity of the organ. In the gland of a woman who is not pregnant or suckling the alveoli are very small and solid, being filled with a mass of granular polyhedral cells. During pregnancy the alveoli enlarge and the cells undergo rapid multiplication. At the commencement of lactation the cells in the centre of the alveolus undergo fatty degeneration, and are eliminated in the first milk as *colostrum-corpuscles*. The peripheral cells of the alveolus remain, and form a single layer of granular, short columnar cells, with a spherical nucleus, lining the limiting *membrana propria*. These cells during the state of activity of the gland are capable of forming, in their interior, oil-globules, which are then ejected into the lumen of the alveolus and constitute the milk-globules.

The *fibrous tissue* invests the entire surface of the breast, and sends down septa between its lobes, connecting them together.

The *fatty tissue* surrounds the surface of the gland and occupies the interval between its lobes. It usually exists in considerable abundance, and determines the form and size of the gland. There is no fat immediately beneath the areola and nipple.

Vessels and Nerves.—The *arteries* supplying the mammae are derived from the thoracic branches of the axillary, the intercostals, and internal mammary. The *veins* describe an anastomotic circle round the base of the nipple, called by Haller the *circulus venosus*. From this large branches transmit the blood to the circumference of the gland and end in the axillary and internal mammary veins. The *lymphatics*, for the most part, run along the lower border of the Pectoralis major to the axillary glands: some few, from the inner side of the breast, perforate the intercostal spaces and empty themselves into the anterior mediastinal glands. The *nerves* are derived from the anterior and lateral cutaneous nerves of the thorax.

THE SURGICAL ANATOMY OF HERNIA.

Dissection (Fig. 621).—For dissection of the parts concerned in inguinal hernia a male subject, free from fat, should always be selected. The body should be placed in the supine position, the abdomen and pelvis raised by means of blocks placed beneath them, and the lower extremities rotated outward, so as to make the parts as tense as possible. If the abdominal walls are flaccid, the cavity of the abdomen should be inflated by an aperture through the umbilicus. An incision should be made along the middle line from the umbilicus to the symphysis pubis, and continued along the front of the scrotum, and a second incision from the anterior superior spine of the ilium to just below the umbilicus. These incisions should divide the integument, and the triangular-shaped flap included between them should be reflected downward and outward, when the superficial fascia will be exposed.

The Superficial Fascia of the Abdomen.—This, over the greater part of the abdominal wall, consists of a single layer of fascia, which contains a variable amount of fat; but as it approaches the groin it is easily divisible into two layers, between which are found the superficial vessels and nerves and the superficial inguinal lymphatic glands.

The *superficial layer* is thick, areolar in texture, containing adipose tissue in its meshes, the quantity of which varies in different subjects. Below, it passes over Poupart's ligament, and is continuous with the outer layer of the superficial fascia of the thigh. In the male this fascia is continued over the penis and over the outer surface of the cord to the scrotum, where it helps to form the dartos. As it passes to the penis and over the cord to the scrotum it changes its character, becoming thin, destitute of adipose tissue, and of a pale reddish color; and in the scrotum it acquires some involuntary muscular fibres. From the scrotum it may be traced backward, to be continuous with the superficial fascia of the perinæum. In the female this fascia is continued into the labia majora.

The *hypogastric branch of the ilio-hypogastric nerve* perforates the aponeurosis of the External oblique muscle about an inch above and a little to the outer side of the external abdominal ring, and is distributed to the integument of the hypogastric region.

The *ilio-inguinal nerve* escapes at the external abdominal ring, and is distributed to the integument of the upper and inner part of the thigh, to the scrotum in the male and to the labium in the female.

The *superficial epigastric artery* arises from the femoral about half an inch below Poupart's ligament, and, passing through the saphenous opening in the fascia lata, ascends on to the abdomen, in the superficial fascia covering the External oblique muscle, nearly as high as the umbilicus. It distributes branches to the superficial inguinal lymphatic glands, the superficial fascia, and the integument, anastomosing with branches of the deep epigastric and internal mammary arteries.

The *superficial circumflex iliac artery*, the smallest of the cutaneous branches, arises close to the preceding, and, piercing the fascia lata, runs outward, parallel with Poupart's ligament, as far as the crest of the ilium, dividing into branches which supply the superficial inguinal lymphatic glands, the superficial fascia, and the integument, anastomosing with the deep circumflex iliac and with the gluteal and external circumflex arteries.

The *superficial external pudic (superior) artery* arises from the inner side of the femoral artery close to the preceding vessels, and, after passing through the saphenous opening, courses inward across the spermatic cord, to be distributed to the integument on the lower part of the abdomen, the penis and scrotum in the male, and the labium in the female, anastomosing with branches of the internal pudic.

The Superficial Veins.—The veins accompanying these superficial vessels are

usually much larger than the arteries; they terminate in the internal saphenous vein.

The *superficial inguinal lymphatic glands* are placed immediately beneath the integument, are of large size, and vary from eight to ten in number. They are divisible into two groups: an upper, disposed irregularly along Poupart's ligament, which receive the lymphatic vessels from the integument of the scrotum, penis, parietes of the abdomen, perineal and gluteal regions, and the mucous membrane of the urethra; and an inferior group, which surround the saphenous opening in the fascia lata, a few being sometimes continued along the saphenous

FIG. 621.—Inguinal hernia. Superficial dissection.

vein to a variable extent. This latter group receive the superficial lymphatic vessels from the lower extremity.

The *deep layer of the superficial fascia* (*fascia of Scarpa*) is thinner and more membranous in character than the superficial layer. In the middle line it is intimately adherent to the linea alba; above, it is continuous with the superficial fascia over the rest of the trunk; below, it blends with the fascia lata of the thigh, a little below Poupart's ligament; below and internally, in the male, it is continued over the penis and over the outer surface of the cord to the scrotum, where it helps to form the dartos. From the scrotum it may be traced backward to be continuous with the deep layer of the superficial fascia of the perinæum. In the female it is continuous with the labia majora.

The scrotum is a cutaneous pouch which contains the testes and part of the spermatic cords, and into which an inguinal hernia frequently descends (see page 1037).

The Aponeurosis of the External Oblique Muscle.—This is a thin but strong

membranous aponeurosis, the fibres of which are directed obliquely downward and inward. That portion of the aponeurosis which extends between the anterior superior spine of the ilium and the spine of the os pubis is a broad band, folded inward and continuous below with the fascia lata; it is called *Poupart's ligament*. The portion which is reflected from Poupart's ligament at the spine of the os pubis, along the pectineal line, is called *Gimbernat's ligament*. From the point of attachment of the latter to the pectineal line a few fibres pass upward and inward, behind the inner pillar of the ring, to the linea alba. They diverge as they ascend, and form a thin, triangular, fibrous band, which is called the *triangular ligament of the abdomen*. In the aponeurosis of the External oblique, immediately above the crest of the os pubis, is a triangular opening, the *external or superficial abdominal ring*, formed by the separation of the fibres of the aponeurosis in this situation.

The External or Superficial Abdominal Ring.—Just above and to the outer side of the crest of the os pubis an interval is seen in the aponeurosis of the External oblique, called the *external abdominal ring*. This aperture is oblique in direction, somewhat triangular in form, and corresponds with the course of the fibres of the aponeurosis. It usually measures from base to apex about an inch, and transversely about half an inch. It is bounded below by the crest of the os pubis; above, by a series of curved fibres, the *intercolumnar*, which pass across the upper angle of the ring, so as to increase its strength; and on either side, by the margins of the opening in the aponeurosis, which are called the *columns or pillars of the ring*.

The *external pillar*, which at the same time is *inferior* from the obliquity of its direction, is the stronger; it is formed by that portion of Poupart's ligament which is inserted into the spine of the os pubis; it is curved, so as to form a kind of groove, upon which the spermatic cord rests.

The *internal or superior pillar* is a broad, thin, flat band, which is attached to the front of the body of the os pubis, interlacing with its fellow of the opposite side in front of the symphysis pubis, that of the right side being superficial.

The external abdominal ring gives passage to the spermatic cord in the male and round ligament in the female; it is much larger in men than in women, on account of the large size of the spermatic cord, and hence the great frequency of inguinal hernia in men.

The *intercolumnar fibres* are a series of curved tendinous fibres which arch across the lower part of the aponeurosis of the External oblique. They have received their name from stretching across between the two pillars of the external ring; they increase the strength of the lower part of the aponeurosis and prevent the divergence of the pillars from one another. They are thickest below, where they are connected to the outer third of Poupart's ligament, and are inserted into the linea alba, describing a curve, with the convexity downward. They are much thicker and stronger at the outer angle of the external ring than internally, and are more strongly developed in the male than in the female. These intercolumnar fibres, as they pass across the external abdominal ring, are themselves connected together by delicate fibrous tissue, thus forming a fascia which, as it is attached to the pillars of the ring, covers it in, and is called the *intercolumnar fascia*. This intercolumnar fascia is continued downward as a tubular prolongation around the outer surface of the cord and testis, and encloses them in a distinct sheath; hence it is also called the *external spermatic fascia*. The sac of an inguinal hernia in passing through the external abdominal ring receives an investment from the intercolumnar fascia.

If the finger is introduced a short distance into the external ring, and then, if the limb is extended and rotated outward, the aponeurosis of the External oblique, together with the iliac portion of the fascia lata, will be felt to become tense and the external ring much contracted; if the limb is, on the contrary, flexed upon the pelvis and rotated inward, this aponeurosis will become lax, and the external ring sufficiently enlarged to admit the finger with comparative ease; hence the patient should always be put in the latter position when the taxis is applied for the reduc-

continuous with Gimbernat's ligament. It passes inward beneath the spermatic cord, and expands into a somewhat fan-shaped fascia, lying behind the inner pillar of the external abdominal ring and in front of the conjoined tendon, and interlaces with the ligament of the other side at the linea alba.

The **Internal oblique muscle** has been previously described (page 453). The part which is now exposed is partly muscular and partly tendinous in structure. Those fibres which arise from Poupart's ligament, few in number and paler in color than the rest, arch downward and inward across the spermatic cord, and, becoming tendinous, are inserted, conjointly with those of the Transversalis, into the crest of the os pubis and pectineal line, forming what is known as the conjoined tendon of the Internal oblique and Transversalis. This tendon is inserted immediately behind the external abdominal ring, serving to protect what would otherwise be a weak point in the abdominal wall. Sometimes this tendon is insufficient to resist the pressure from within, and is carried forward in front of the protrusion through the external ring, forming one of the coverings of direct inguinal hernia, or the hernia forces its way through the fibres of the conjoined tendon.

The **Cremaster** is a thin muscular layer composed of a number of fasciculi which arise from the middle of Poupart's ligament at the inner side of the Internal oblique, being connected with that muscle and also occasionally with the Transversalis. It passes along the outer side of the spermatic cord, descends with it through the external ring upon the front and sides of the cord, and forms a series of loops which differ in thickness and length in different subjects. Those at the upper part of the cord are exceedingly short, but they become in succession longer and longer, the longest reaching down as low as the testicle, where a few are inserted into the tunica vaginalis. These loops are united together by areolar tissue, and form a thin covering over the cord and testis, the *fascia cremasterica*. The fibres ascend along the inner side of the cord, and are inserted by a small pointed tendon into the crest of the os pubis and front of the sheath of the Rectus muscle.

It will be observed that the origin and insertion of the Cremaster is precisely similar to that of the lower fibres of the Internal oblique. This fact affords an easy explanation of the manner in which the testicle and cord are invested by this muscle. At an early period of foetal life the testis is placed at the lower and back part of the abdominal cavity, but during its descent toward the scrotum, which takes place before birth, it passes beneath the arched border of the Internal oblique. In its passage beneath this muscle some fibres are derived from its lower part which accompany the testicle and cord into the scrotum.

It occasionally happens that the loops of the Cremaster surround the cord, some lying behind as well as in front. It is probable that under these circumstances the testis in its descent passes through, instead of beneath, the fibres of the Internal oblique.

In the descent of an oblique inguinal hernia, which takes the same course as the spermatic cord, the Cremaster muscle forms one of its coverings. This muscle becomes largely developed in cases of hydrocele and large old scrotal herniæ. No such muscle exists in the female, but an analogous structure is developed in those cases where an oblique inguinal hernia descends beneath the margin of the Internal oblique.

The Internal oblique should be detached from Poupart's ligament, separated from the Transversalis to the same extent as in the previous incisions, and reflected inward on to the sheath of the Rectus (Fig. 623). The circumflex iliac vessels, which lie between these two muscles, form a valuable guide to their separation.

The **Transversalis muscle** has been previously described (page 455). The part which is now exposed is partly muscular and partly tendinous in structure; this portion arises from the outer third of Poupart's ligament, its fibres curve downward and inward, and are inserted, together with those of the Internal oblique, into the lower part of the linea alba, into the crest of the os pubis and pectineal line, forming what is known as the conjoined tendon of the Internal oblique and

Transversalis. Between the lower border of this muscle and Poupart's ligament a space is left in which is seen the fascia transversalis.

The **inguinal** or **spermatic canal** contains the spermatic cord in the male and the round ligament in the female. It is an oblique canal, about an inch and a half in length, directed downward and inward and placed parallel with, and a little above, Poupart's ligament. It commences above at the internal abdominal ring, which is the point where the cord enters the spermatic canal, and terminates below at the external ring. It is bounded, *in front*, by the integument and superficial fascia, by the aponeurosis of the External oblique throughout its whole length, and by the Internal oblique for its outer third; *behind*, by the triangular ligament, the conjoined tendon of the Internal oblique and Transversalis, transversalis fascia, and the subperitoneal fat and peritoneum; *above*, by the arched fibres of the Internal oblique and Transversalis; *below*, by the union of the fascia transversalis with Poupart's ligament. That form of protrusion in which the

FIG. 623.—Inguinal hernia showing the Transversalis muscle, the transversalis fascia, and the internal abdominal ring.

intestine follows the course of the spermatic cord along the spermatic canal is called *oblique inguinal hernia*.

The **fascia transversalis** is a thin aponeurotic membrane which lies between the inner surface of the Transversalis muscle and the peritoneum. It forms part of the general layer of fascia which lines the interior of the abdominal and pelvic cavities, and is directly continuous with the iliac and pelvic fasciæ.

In the inguinal region the transversalis fascia is thick and dense in structure, and joined by fibres from the aponeurosis of the Transversalis muscle; but it becomes thin and cellular as it ascends to the Diaphragm. Below, it has the following attachments: external to the femoral vessels it is connected to the posterior margin of Poupart's ligament, and is there continuous with the iliac fascia. Internal to the vessels it is thin, and attached to the os pubis and pectineal line behind the conjoined tendon, with which it is united; and, corresponding to the points where the femoral vessels pass into the thigh, this fascia descends in front of them, forming the anterior wall of the crural sheath. The spermatic cord

in the male and the round ligament in the female pass the point where they pass through is called the internal or deep opening is not visible externally, owing to a prolongation of on these structures, forming the infundibuliform process.

The **internal or deep abdominal ring** is situated in midway between the anterior superior spine of the ilium and about half an inch above Poupart's ligament. Its extremities of the oval directed upward and downward; different subjects, and is much larger in the male than in the female. It is bounded above and externally by the arched fibres of the Transversalis internally by the deep epigastric vessels. It transmits the male and the round ligament in the female. From its funnel-shaped membrane, the *infundibuliform fascia*, is cut and testis, enclosing them in a distinct pouch. When an inguinal hernia passes through the internal or deep abdominal buliform process of the transversalis fascia forms one of its

The Subperitoneal Areolar Tissue.—Between the fasci peritoneum is a quantity of loose areolar tissue. In some considerable thickness and loaded with adipose tissue. Opposite is continued round the surface of the cord, forming a loose

The *deep epigastric artery* arises from the external iliac Poupart's ligament. It at first descends to reach this ligament obliquely along the inner margin of the internal or deep between the transversalis fascia and the peritoneum, and the transversalis fascia and enters the sheath of the Rectum semilunar fold of Douglas. Consequently the deep epigastric important relation to the internal abdominal ring as it passes and inward from its origin from the external iliac. In the female lies along the lower and inner margin of the internal commencement of the spermatic cord. As it winds round the ring it is crossed by the vas deferens in the male and by the female.

The **peritoneum**, corresponding to the inner surface of the a well-marked depression, the depth of which varies in different fibrous band is continued from it along the front of the cord and becomes ultimately lost. This is the remains of the which, in the fœtus, accompanies the cord and testis obliteration of which commences soon after birth. In some can only be traced a short distance, but occasionally it may cord, as far as the upper end of the tunica vaginalis. The peritoneum is only closed at intervals and presents a sac-like single pouch may extend along the whole length of the cord above, or the pouch may be directly continuous with the opening at its upper part.

In the female (in the fœtus) the peritoneum is also present as a tubular process for a short distance into the inguinal canal the canal of Nuck. It is generally obliterated in the adult, but pervious even in advanced life. It is analogous to the which accompanies the descent of the testis.

INGUINAL HERNIA.

Inguinal hernia is that form of protrusion which makes its way into the abdomen in the inguinal region.

There are two principal varieties of inguinal hernia—**internal or direct.**

External or oblique inguinal hernia, the more frequent

same course as the spermatic cord. It is called *external* from the neck of the sac being on the outer or iliac side of the deep epigastric artery.

Internal or direct inguinal hernia does not follow the same course as the cord, but protrudes through the abdominal wall on the inner or pubic side of the deep epigastric artery.

Oblique Inguinal Hernia.

In **oblique inguinal hernia** the intestine escapes from the abdominal cavity at the internal ring, pushing before it a pouch of peritoneum, which forms the hernial

FIG. 624.—Oblique inguinal hernia, showing its various coverings. (From a preparation in the Museum of the Royal College of Surgeons.)

sac (Fig. 625, A). As it enters the inguinal canal it receives an investment from the subserous areolar tissue, and is enclosed in the infundibuliform process of the transversalis fascia. In passing along the inguinal canal it displaces upward the arched fibres of the Transversalis and Internal oblique muscles, and is surrounded by the fibres of the Cremaster. It then passes along the front of the cord, and escapes from the inguinal canal at the external ring, receiving an investment from the intercolumnar fascia. Lastly, it descends into the scrotum, receiving coverings from the superficial fascia and the integument.

The coverings of this form of hernia, after it has passed through the external ring, are, from without inward, the integument, superficial fascia, intercolumnar fascia, Cremaster muscle, infundibuliform fascia, subserous areolar tissue, and peritoneum.

This form of hernia lies in front of the vessels of the spermatic cord and

seldom extends below the testis, on account of the intimate adhesion of the coverings of the cord to the tunica vaginalis.

FIG. 625.—Varieties of oblique inguinal hernia.

The seat of stricture in oblique inguinal hernia is either at the external ring in the inguinal canal, caused by the fibres of the Internal oblique or Trans

versalis; or at the internal ring, most frequently in the latter situation. If it is situated at the external ring, the division of a few fibres at one point of its circumference is all that is necessary for the replacement of the hernia. If in the inguinal canal or at the internal ring, it may be necessary to divide the aponeurosis of the External oblique so as to lay open the inguinal canal. In dividing the stricture the direction of the incision should be upward.

When the intestine passes along the spermatic canal and escapes from the external ring into the scrotum, it is called *complete oblique inguinal* or *scrotal hernia*. If the intestine does not escape from the external ring, but is retained in the inguinal canal, it is called *incomplete inguinal hernia*, or *bubonocoele*. In each of these cases the coverings which invest it will depend upon the extent to which it descends in the inguinal canal.

There are some other varieties of oblique inguinal hernia depending upon congenital defects in the processus vaginalis. The testicle in its descent from the abdomen into the scrotum is accompanied by a pouch of peritoneum, which about the period of birth becomes shut off from the general peritoneal cavity by a closure of that portion of the pouch which extends from the internal abdominal ring to near the upper part of the testicle, the lower portion of the pouch remaining persistent as the tunica vaginalis. It would appear that this closure commences at two points—viz. at the internal abdominal ring and at the top of the epididymis—and gradually extends until, in the normal condition, the whole of the intervening portion is converted into a fibrous cord. From failure in the completion of this process variations in the relation of the hernial protrusion to the testicle and tunica vaginalis are produced, which constitute distinct varieties of inguinal hernia, and which have received separate names and are of surgical importance. These are congenital, infantile, encysted, and hernia of the funicular process.

Congenital Hernia (Fig. 625, B).—Where the pouch of peritoneum which accompanies the cord and testis in its descent remains patent throughout and is unclosed at any point, the cavity of the tunica vaginalis communicates directly with the peritoneum. The intestine descends along this pouch into the cavity of the tunica vaginalis, which constitutes the sac of the hernia, and the gut lies in contact with the testicle.

Infantile and Encysted Hernia.—Where the pouch of peritoneum is occluded at the internal ring only, and remains patent throughout the rest of its extent, two varieties of oblique inguinal hernia may be produced, which have received the names of infantile and encysted hernia. In the *infantile* form (Fig. 625, c) the bowel, pressing upon the septum and the peritoneum in its immediate neighborhood, causes it to yield and form a sac, which descends behind the tunica vaginalis, so that in front of the bowel there are three layers of peritoneum, the two layers of the tunica vaginalis and its own sac. In the *encysted* form (Fig. 625, D) pressure in the same position—namely, at the occluded spot in the pouch—causes the septum to yield and form a sac which projects *into* and not *behind* the tunica vaginalis, as in the infantile form, and thus it constitutes a sac within a sac, so that in front of the bowel there are two layers of peritoneum—one layer of the tunica vaginalis and its own sac.

Hernia into the Funicular Process (Fig. 625, E).—Where the pouch of peritoneum is occluded at the lower point only—that is, just above the testicle—the intestine descends into the pouch of peritoneum as far as the testicle, but is prevented from entering the sac of the tunica vaginalis by the septum which has formed between it and the pouch, so that it resembles the congenital form in all respects, except that, instead of enveloping the testicle, that body can be felt below the rupture.

Direct Inguinal Hernia.

In *direct inguinal hernia* the protrusion makes its way through some part of the abdominal wall internal to the epigastric artery.

At the lower part of the abdominal wall is a triangular space (*Hesselbach's triangle*) bounded externally by the deep epigastric artery, internally by the margin of the Rectus muscle, below by Poupart's ligament. The conjoined tendon is stretched across the inner two-thirds of this space, the remaining portion of the space having only the subperitoneal areolar tissue and the transversalis fascia between the peritoneum and the aponeurosis of the External oblique muscle.

In some cases the hernial protrusion escapes from the abdomen on the outer side of the conjoined tendon, pushing before it the peritoneum, the subserous areolar tissue, and the transversalis fascia. It then enters the inguinal canal, passing along nearly its whole length, and finally emerges from the external ring, receiving an investment from the intercolumnar fascia. The coverings of this form of hernia are precisely similar to those investing the oblique form, with the insignificant difference that the infundibuliform fascia is replaced by a portion derived from the general layer of the fascia transversalis.

In other cases—and this is the more frequent variety—the hernia is either forced through the fibres of the conjoined tendon or the tendon is gradually distended in front of it so as to form a complete investment for it. The intestine then enters the lower end of the inguinal canal, escapes at the external ring lying on the inner side of the cord, and receives additional coverings from the superficial fascia and the integument. This form of hernia has the same coverings as the oblique variety, excepting that the conjoined tendon is substituted for the Cremaster, and the infundibuliform fascia is replaced by a portion derived from the general layer of the fascia transversalis.

The difference between the position of the neck of the sac in these two forms of direct inguinal hernia has been referred, with some probability, to a difference in the relative positions of the obliterated hypogastric artery and the deep epigastric artery. When the course of the obliterated hypogastric artery corresponds pretty nearly with that of the deep epigastric—which is regarded as the normal arrangement—the projection of these arteries toward the cavity of the abdomen produces two fossæ in the peritoneum. The bottom of the external fossa of the peritoneum corresponds to the position of the internal abdominal ring, and a hernia which distends and pushes out the peritoneum lining this fossa is an oblique hernia. When, on the other hand, the obliterated hypogastric artery lies considerably to the inner side of the deep epigastric artery, corresponding to the outer margin of the conjoined tendon, it divides the triangle of Hesselbach into two parts, so that three depressions will be seen on the inner surface of the lower part of the abdominal wall—viz. an external one, on the outer side of the deep epigastric artery; a middle one, between the deep epigastric and the obliterated hypogastric arteries; and an internal one, on the inner side of the obliterated hypogastric artery. In such a case a hernia may distend and push out the peritoneum forming the bottom of either fossa. When the hernia distends and pushes out the peritoneum forming the bottom of the external fossa, it is an oblique or external inguinal hernia.

When the hernia distends and pushes out the peritoneum forming the bottom of either the middle or the internal fossa, it is a direct or internal hernia.

The anatomical difference between these two forms of direct or internal inguinal hernia is that, when the hernia protrudes through the middle fossa—that is, the fossa between the deep epigastric and the obliterated hypogastric arteries—it will enter the upper part of the inguinal canal; consequently its coverings will be the same as those of an oblique hernia, with the insignificant difference that the infundibuliform fascia is replaced by a portion derived from the general layer of the fascia transversalis, whereas when the hernia protrudes through the internal fossa it is either forced through the fibres of the conjoined tendon or the tendon is gradually distended in front of it so as to form a complete investment for it. The intestine then enters the lower part of the inguinal canal, and escapes from the external abdominal ring lying on the inner side of the cord.

This form of hernia has the same coverings as the oblique variety, excepting that the conjoined tendon is substituted for the Cremaster, and the infundibuliform fascia is replaced by a portion derived from the general layer of the fascia transversalis.

The *seat of stricture* in both varieties of direct hernia is most frequently at the neck of the sac or at the external ring. In that form of hernia which perforates the conjoined tendon it not unfrequently occurs at the edges of the fissure through which the gut passes. In dividing the stricture the incision should in all cases be directed upward.¹

If the hernial protrusion passes into the inguinal canal, but does not escape from the external abdominal ring, it forms what is called *incomplete direct hernia*. This form of hernia is usually of small size, and in corpulent persons very difficult of detection.

Direct inguinal hernia is of much less frequent occurrence than the oblique, their comparative frequency being, according to Cloquet, as one to five. It occurs far more frequently in men than in women, on account of the larger size of the external ring in the former sex. It differs from the oblique in its smaller size and globular form, dependent most probably on the resistance offered to its progress by the transversalis fascia and conjoined tendon. It differs also in its position, being placed over the os pubis and not in the course of the inguinal canal. The deep epigastric artery runs on the outer or iliac side of the neck of the sac, and the spermatic cord along its external and posterior side, not directly behind it, as in oblique inguinal hernia.

FEMORAL HERNIA.

The dissection of the parts comprised in the anatomy of femoral hernia should be performed, if possible, upon a female subject free from fat. The subject should lie upon its back; a block is first placed under the pelvis, the thigh everted, and the knee slightly bent and retained in this position. An incision should then be made from the anterior superior spinous process of the ilium along Poupart's ligament to the symphysis pubis; a second incision should be carried transversely across the thigh about six inches beneath the preceding; and these are to be connected together by a vertical one carried along the inner side of the thigh. These several incisions should divide merely the integument; this is to be reflected outward, when the superficial fascia will be exposed.

The *superficial fascia* forms a continuous layer over the whole of the thigh, consisting of areolar tissue, containing in its meshes much fat, and capable of being separated into two or more layers, between which are found the superficial vessels and nerves. It varies in thickness in different parts of the limb. In the groin it is thick, and the two layers are separated from one another by the superficial inguinal lymphatic glands, the internal saphenous vein, and several smaller vessels. One of these layers, the superficial, is continuous with the superficial fascia of the abdomen.

The superficial layer should be detached by dividing it across in the same direction as the external incisions; its removal will be facilitated by commencing at the lower and inner angle of the space, detaching it at first from the front of the internal saphenous vein, and dissecting it off from the anterior surface of that vessel and its tributaries; it should then be reflected outward in the same manner as the integument. The cutaneous vessels and nerves and superficial inguinal glands are then exposed, lying upon the deep layer of the superficial fascia. These are the internal saphenous vein and the superficial epigastric, superficial circumflex iliac, and superficial external pudic vessels, as well as numerous lymphatics, ascending with the saphenous vein to the inguinal glands.

The *internal or long saphenous vein* ascends along the inner side of the thigh, and, passing through the saphenous opening in the fascia lata, terminates in the femoral vein about an inch and a half below Poupart's ligament. This vein

¹ In all cases of inguinal hernia, whether oblique or direct, it is proper to divide the stricture directly upward: the reason of this is obvious, for by cutting in this direction the incision is made parallel to the deep epigastric artery—either external to it in the oblique variety, or internal to it in the direct form of hernia—and thus all chance of wounding the vessel is avoided. If the incision was made outward, the artery might be divided if the hernia was direct; and if made inward, it would stand an equal chance of injury if the case was one of oblique inguinal hernia.

The *superficial inguinal lymphatic glands*, placed immediately beneath the integument, are of large size and vary from eight to ten in number. They are divisible into two groups: an upper, disposed irregularly along Poupart's ligament, which receive the lymphatic vessels from the integument of the scrotum, penis, parietes of the abdomen, perineal and gluteal regions, and the mucous membrane of the urethra; and an inferior group, which surround the saphenous opening in the fascia lata, a few being sometimes continued along the saphenous vein to a variable extent. This latter group receive the superficial lymphatic vessels from the lower extremity.

The *ilio-inguinal nerve* arises from the first lumbar nerve. It escapes at the external abdominal ring, and is distributed to the integument of the upper and inner part of the thigh—to the scrotum in the male and to the labium in the female. The size of this nerve is in inverse proportion to that of the ilio-hypogastric. Occasionally it is very small, and ends by joining the ilio-hypogastric: in such cases a branch of the ilio-hypogastric takes the place of the ilio-inguinal, or the latter nerve may be altogether absent. The *crural branch of the genito-crural nerve* passes along the inner margin of the Psoas muscle, beneath Poupart's ligament, into the thigh, entering the sheath of the femoral vessels, and lying superficial and a little external to the femoral artery. It pierces the anterior layer of the sheath of the vessels, and, becoming superficial by passing through the fascia lata, it supplies the skin of the anterior aspect of the thigh as far as midway between the pelvis and knee. On the front of the thigh it communicates with the outer branch of the middle cutaneous nerve, derived from the anterior crural.

The *deep layer of the superficial fascia* is a very thin fibrous layer, best marked on the inner side of the long saphenous vein and below Poupart's ligament. It is placed beneath the subcutaneous vessels and nerves, and upon the surface of the fascia lata, to which it is intimately adherent at the lower margin of Poupart's ligament. It covers the saphenous opening in the fascia lata, is closely united to its circumference, and is connected to the sheath of the femoral vessels corresponding to its under surface. The portion of fascia covering this aperture is perforated by the internal saphenous vein and by numerous blood- and lymphatic vessels; hence it has been termed the *cribriform fascia*, the openings for these vessels having been likened to the holes in a sieve. The cribriform fascia adheres closely both to the superficial fascia and to the fascia lata, so that it is described by some anatomists as a part of the fascia lata, but it is usually considered (as in this work) as belonging to the superficial fascia. It is not till the cribriform fascia has been cleared away that the saphenous opening is seen, so that this opening does not in ordinary cases exist naturally, but is the result of dissection. A femoral hernia in passing through the saphenous opening receives the cribriform fascia as one of its coverings.

The deep layer of superficial fascia, together with the cribriform fascia, having been removed, the fascia lata is exposed.

The **Fascia Lata** has been already described with the muscles of the front of the thigh (page 508). At the upper and inner part of the thigh, a little below Poupart's ligament, a large oval-shaped aperture is observed after the superficial fascia has been cleared away; it transmits the internal saphenous vein and other smaller vessels, and is called the *saphenous opening*. In order the more correctly to consider the mode of formation of this aperture, the fascia lata in this part of the thigh is described as consisting of two portions, an iliac portion and a pubic portion.

The *iliac portion* is all that part of the fascia lata on the outer side of the saphenous opening. It is attached externally to the crest of the ilium and its anterior superior spine; to the whole length of Poupart's ligament as far internally as the spine of the os pubis; and to the pectineal line in conjunction with Gimbernat's ligament. From the spine of the os pubis it is reflected downward and outward, forming an arched margin, the outer boundary or falciform process or superior cornu of the saphenous opening. This margin overlies and is adherent to the anterior layer of the sheath of the femoral vessels; to its edge is attached the

cribriform fascia, and below it is continuous with the pubic portion of the fascia lata.

The *pubic portion of the fascia lata* is situated at the inner side of the saphenous opening: at the lower margin of this aperture it is continuous with the iliac portion: traced upward, it covers the surface of the Pectineus, Adductor longus, and Gracilis muscles; and, passing behind the sheath of the femoral vessels, to which it is closely united, is continuous with the sheath of the Psoas and Iliacus muscles, and is attached above to the ilio-pectineal line, where it becomes continuous with the fascia covering the Iliacus muscle. From this description it may be observed that the iliac portion of the fascia lata passes in front of the femoral vessels and the pubic portion behind them, so that an apparent aperture

FIG. 627.—Femoral hernia, showing fascia lata and saphenous opening.

consequently exists between the two, through which the internal saphenous joins the femoral vein.

The **Saphenous Opening** is an oval-shaped aperture measuring about an inch and a half in length and half an inch in width. It is situated at the upper and inner part of the front of the thigh, below Poupart's ligament, and is directed obliquely downward and outward.

Its *outer margin* is of a semilunar form, thin, strong, sharply defined, and lies on a plane considerably anterior to the inner margin. If this edge is traced upward, it will be seen to form a curved elongated process, the *falciform process* or *superior cornu*, which ascends in front of the femoral vessels, and, curving inward, is attached to Poupart's ligament and to the spine of the os pubis and pectineal line, where it is continuous with the pubic portion. If traced downward, it is found continuous with another curved margin, the concavity of which is directed upward and inward: this is the inferior cornu of the saphenous

opening, and is blended with the pubic portion of the fascia lata covering the Pectineus muscle.

The *inner boundary of the opening* is on a plane posterior to the outer margin and behind the level of the femoral vessels; it is much less prominent and defined than the outer, from being stretched over the subjacent Pectineus muscle. It is through the saphenous opening that a femoral hernia passes after descending along the crural canal.

If the finger is introduced into the saphenous opening while the limb is moved in different directions, the aperture will be found to be greatly constricted on extending the limb or rotating it outward, and to be relaxed on flexing the limb

FIG. 628.—Femoral hernia. Iliac portion of fascia lata removed, and sheath of femoral vessels and femoral canal exposed.

and inverting it: hence the necessity for placing the limb in the latter position in employing the taxis for the reduction of a femoral hernia.

The iliac portion of the fascia lata, but not its falciform process, should now be removed by detaching it from the lower margin of Poupart's ligament, carefully dissecting it from the subjacent structures, and turning it inward, when the sheath of the femoral vessels is exposed, descending beneath Poupart's ligament (Fig. 628).

Poupart's Ligament, or the **Crural Arch**, is the lower border of the aponeurosis of the External oblique muscle, which extends from the anterior superior spine of the ilium to the spine of the os pubis. From this latter point it is reflected outward, to be attached to the pectineal line for about half an inch, forming Gimbernat's ligament. Its general direction is curved downward toward the thigh, where it is continuous with the fascia lata. Its outer half is rounded and oblique in direction. Its inner half gradually widens at its attachment to the os pubis, is more horizontal in direction, and lies beneath the spermatic cord. Nearly the

whole of the space included between the crural arch and innominate bone is filled in by the parts which descend from the abdomen into the thigh. The outer half of the space is occupied by the Iliacus and Psoas muscles, together with the external cutaneous and anterior crural nerves. The pubic half of the space is occupied by the femoral vessels included in their sheath, a small oval-shaped interval existing between the femoral vein and the inner wall of the sheath, which is occupied merely by a little loose areolar tissue, a few lymphatic vessels.

FIG. 629.—Structures which pass beneath the crural arch.

and occasionally by a small lymphatic gland: this is the crural ring, through which the gut descends in femoral hernia.

Gimbernat's Ligament (Fig. 630) is that part of the aponeurosis of the External oblique muscle which is reflected downward and outward from the spine of the os pubis, to be inserted into the pectineal line. It is about half an inch in length, larger in the male than in the female, almost horizontal in direction in the erect posture, and of a triangular form, with the base directed outward. Its *base*, or outer margin, is concave, thin, and sharp, and lies in contact with the crural sheath. Its *apex* corresponds to the spine of the os pubis. Its *posterior margin* is attached to the pectineal line, and is continuous with the pubic portion of the fascia lata. Its *anterior margin* is continuous with Poupart's ligament.

Crural Sheath.—The femoral or crural sheath is a continuation downward of the fasciæ that line the abdomen, the transversalis fascia passing down in front of the femoral vessels, and the iliac fascia descending behind them; these fasciæ are directly continuous on the iliac side of the femoral artery, but a small space exists between the femoral vein and the point where they are continuous on the iliac side of that vessel, which constitutes the femoral or crural canal. The

femoral sheath is closely adherent to the contained vessels about an inch below the saphenous opening, being blended with the areolar sheath of the vessels, but opposite Poupart's ligament it is much larger than is required to contain them; hence the funnel-shaped form which it presents. The outer border of the sheath is perforated by the genito-crural nerve. Its inner border is pierced by the internal saphenous vein and numerous lymphatic vessels. In front it is covered by the iliac portion of the fascia lata; and behind it is the pubic portion of the same fascia.

If the anterior wall of the sheath is removed, the femoral artery and vein are seen lying side by side, a thin septum separating the two vessels, while another septum may be seen lying just internal to the vein, and cutting off a small space between the vein and the inner wall of the sheath. The septa are stretched between the anterior and posterior walls of the sheath, so that each vessel is enclosed in a separate compartment. The interval left between the vein and the inner wall of the sheath is not filled up by any structure, excepting a little loose areolar tissue, a few lymphatic vessels, and occasionally by a small lymphatic

FIG. 630.—Hernia. The relations of the femoral and internal abdominal rings, seen from within the abdomen. Right side.

gland: this is the femoral or crural canal, through which the intestine descends in femoral hernia.

Deep Crural Arch.—Passing across the front of the crural sheath on the abdominal side of Poupart's ligament, and closely connected with it, is a thickened band of fibres called the *deep crural arch*. It is apparently a thickening of the fascia transversalis, joining externally to the centre of Poupart's ligament, and arching across the front of the crural sheath, to be inserted by a broad attachment into the pectineal line behind the conjoined tendon. In some subjects this structure is not very prominently marked, and not unfrequently it is altogether wanting.

The **crural canal** is the narrow interval between the femoral vein and the inner wall of the crural sheath. It exists as a distinct canal only when the sheath has been separated from the vein by dissection or by the pressure of a hernia or tumor. Its length is from a quarter to half an inch, and it extends from Gimbernat's ligament to the upper part of the saphenous opening.

Its *anterior wall* is very narrow, and formed by a continuation downward of the fascia transversalis, under Poupart's ligament, covered by the falciform process of the fascia lata.

Its *posterior wall* is formed by a continuation downward of the iliac fascia covering the pubic portion of the fascia lata.

Its *outer wall* is formed by the fibrous septum separating it from the inner side of the femoral vein.

Its *inner wall* is formed by the junction of the processes of the transversalis and iliac fasciæ, which form the inner side of the femoral sheath, and lies in contact at its commencement with the outer edge of Gimbernat's ligament.

This canal has two orifices—an upper one, the *femoral or crural ring*, closed by the septum crurale; and a lower one, the *saphenous opening*, closed by the cribriform fascia.

The *femoral or crural ring* (Fig. 630) is the upper opening of the femoral canal, and leads into the cavity of the abdomen. It is bounded in front by Poupart's ligament and the deep crural arch; behind, by the os pubis, covered by the Pectineus muscle and the pubic portion of the fascia lata; internally, by the base of Gimbernat's ligament, the conjoined tendon, the transversalis fascia, and the deep crural arch; externally, by the fibrous septum lying on the inner side of the femoral vein. The femoral ring is of an oval form; its long diameter, directed transversely, measures about half an inch, and it is larger in the female than in the male, which is one of the reasons of the greater frequency of femoral hernia in the former sex.

Position of Parts around the Ring.—The spermatic cord in the male and round ligament in the female lie immediately above the anterior margin of the femoral ring, and may be divided in an operation for femoral hernia if the incision for the relief of the stricture is not of limited extent. In the female this is of little importance, but in the male the spermatic artery and vas deferens may be divided.

The *femoral vein* lies on the outer side of the ring.

The *deep epigastric artery* in its passage upward and inward from the external iliac artery passes across the upper and outer angle of the crural ring, and is consequently in danger of being wounded if the stricture is divided in a direction upward and outward.

The *communicating branch* between the deep epigastric and obturator lies in front of the ring.

The circumference of the ring is thus seen to be bounded by vessels in every part, excepting internally and behind. It is in the former position that the stricture is divided in cases of strangulated femoral hernia.

The *obturator artery*, when it arises by a common trunk with the deep epigastric, which occurs once in every three subjects and a half, bears a very important relation to the crural ring. In some cases it descends on the inner side of the external iliac vein to the obturator foramen, and will consequently lie on the outer side of the crural ring, where there is no danger of its being wounded in the operation for dividing the stricture in femoral hernia (see Fig. 373, page 625, fig. A). Occasionally, however, the obturator artery curves along the free margin of Gimbernat's ligament in its passage to the obturator foramen: it would consequently skirt along the greater part of the circumference of the crural ring, and could hardly avoid being wounded in the operation (see Fig. 373, page 625, fig. B).

Septum Crurale.—The femoral ring is closed by a layer of condensed areolar tissue called, by J. Cloquet, the *septum crurale*. This serves as a barrier to the protrusion of a hernia through this part. Its upper surface is slightly concave, and supports a small lymphatic gland by which it is separated from the subserous areolar tissue and peritoneum. Its under surface is turned toward the femoral canal. The septum crurale is perforated by numerous apertures for the passage of lymphatic vessels connecting the deep inguinal lymphatic glands with those surrounding the external iliac artery.

The size of the femoral canal, the degree of tension of its orifices, and consequently the degree of constriction of a hernia, vary according to the position of the leg and thigh. If the leg and thigh are extended, abducted, or everted, the femoral

canal and its orifices are rendered tense from the traction on these parts by Poupart's ligament and the fascia lata, as may be ascertained by passing the finger along the canal. If, on the contrary, the thigh is flexed upon the pelvis, and at the same time adducted and rotated inward, the femoral canal and its orifices become considerably relaxed; for this reason the limb should always be placed in the latter position when the application of the taxis is made in attempting the reduction of a femoral hernia.

The *subperitoneal areolar tissue* is continuous with the subserous areolar tissue of surrounding parts. It is usually thickest and most fibrous where the iliac vessels leave the abdominal cavity. It covers over the small interval (crural ring) on the inner side of the femoral vein. In some subjects it contains a considerable amount of adipose tissue. In such cases, where it is protruded forward in front of the sac of a femoral hernia, it may be mistaken for a portion of omentum. The peritoneum lining the portion of the abdominal wall between Poupart's ligament and the brim of the pelvis is similar to that lining any other portion of the abdominal wall, being very thin. It has here no natural aperture for the escape of intestine.

Descent of the Hernia.—From the preceding description it follows that the femoral ring must be a weak point in the abdominal wall; hence it is that when violent or long-continued pressure is made upon the abdominal viscera a portion of intestine may be forced into it, constituting a femoral hernia; and the changes in the tissues of the abdomen which are produced by pregnancy, together with the larger size of this aperture in the female, serve to explain the frequency of this form of hernia in women.

When a portion of the intestine is forced through the femoral ring, it carries before it a pouch of peritoneum, which forms what is called the *hernial sac*; it receives an investment from the subserous areolar tissue and from the septum crurale, and descends vertically along the crural canal in the inner compartment of the sheath of the femoral vessels as far as the saphenous opening; at this point it changes its course, being prevented from extending farther down the sheath on account of the narrowing of the sheath and its close contact with the vessels, and also from the close attachment of the superficial fascia and crural sheath to the lower part of the circumference of the saphenous opening; the tumor is consequently directed forward, pushing before it the cribriform fascia, and then curves upward on to the falciform process of the fascia lata and lower part of the tendon of the External oblique, being covered by the superficial fascia and integument. While the hernia is contained in the femoral canal it is usually of small size, owing to the resisting nature of the surrounding parts; but when it has escaped from the saphenous opening into the loose areolar tissue of the groin, it becomes considerably enlarged. The direction taken by a femoral hernia in its descent is at first downward, then forward and upward; this should be borne in mind, as in the application of the taxis for the reduction of a femoral hernia pressure should be directed in the reverse order.

Coverings of the Hernia.—The coverings of a femoral hernia, from within outward, are—peritoneum, subserous areolar tissue, the septum crurale, crural sheath, cribriform fascia, superficial fascia, and integument.¹

Varieties of Femoral Hernia.—If the intestine descends along the femoral canal only as far as the saphenous opening, and does not escape from this aperture, it is called *incomplete femoral hernia*. The small size of the protrusion in this form of hernia, on account of the firm and resisting nature of the canal in which it is contained, renders it an exceedingly dangerous variety of the disease, from the

¹ Sir Astley Cooper has described an investment for femoral hernia, under the name of "*fascia propria*," lying immediately external to the peritoneal sac, but frequently separated from it by more or less adipose tissue. Surgically, it is important to remember the existence (at any rate, the occasional existence) of this layer, on account of the ease with which an inexperienced operator may mistake the fascia for the peritoneal sac and the contained fat for omentum. Anatomically, this fascia appears identical with what is called in the text "*subserous areolar tissue*," the areolar tissue being thickened and caused to assume a membranous appearance by the pressure of the hernia.

extreme difficulty of detecting the existence of the swelling in subjects. The coverings of an incomplete femoral hernia are the integument, superficial fascia, falciform process, sheath, septum crurale, subserous areolar tissue, and peritoneum. If the hernial tumor protrudes through the saphenous opening and forward and upward, it forms a *complete femoral hernia*. The hernial sac descends on the iliac side of the femoral vessels or in front of them, and even sometimes behind them.

The *seat of stricture of a femoral hernia* varies: it may be at the neck of the hernial sac; in the greater number of cases it is at the point of junction of the falciform process of the peritoneum with the lunated edge of Gimbernat's ligament, or at the margin of the femoral ring in the thigh. The stricture should in every case be divided, and the extent necessary in the majority of cases is three lines. By these means all vessels or other structures in relation with the neck of the hernial sac will be avoided.

SURGICAL ANATOMY OF THE ISCHIO-RECTAL REGION AND PERINÆUM.

Dissection.—The student should select a well-developed muscular subject, free from fat, and the dissection should be commenced early, in order that the parts may be examined in as recent a state as possible. A staff having been introduced into the bladder and the subject placed in the position shown in Fig. 631, the scrotum should be raised upward, and retained in that position, and the rectum moderately distended with tow.

The space which is now to be examined corresponds to the inferior aperture or outlet of the pelvis. Its deep boundaries are, in front, the pubic arch and subpubic ligament; behind, the tip of the coccyx; and on each side, the rami of the pubes and ischium, the tuberosities of the ischium, and great sacro-sciatic ligaments. The space included by these boundaries is somewhat lozenge-shaped, and is limited on the surface of the body by the scrotum in front, by the buttocks behind, and on each side by the inner side of the thighs. A line drawn transversely between the anterior part of the tuberosity of the ischium on each side, in front of the anus, divides this space into two portions. The anterior portion contains the penis and urethra, and is called the *perinæum*. The posterior portion contains the termination of the rectum, and is called the *ischio-rectal region*.

THE ISCHIO-RECTAL REGION.

The ischio-rectal region corresponds to the portion of the outlet of the pelvis situated immediately behind the perinæum: it contains the termination of the rectum and a deep fossa, filled with fat, on each side of the intestine, between it and the tuberosity of the ischium: this is called the *ischio-rectal fossa*.

The *ischio-rectal region* presents in the middle line the *aperture of the anus*: around this orifice the integument is thrown into numerous folds, which are obliterated on distension of the intestine. The integument is of a dark color, continuous with the mucous membrane of the rectum, and provided with numerous follicles, which occasionally inflame and suppurate, and may be mistaken for fistulæ. The veins around the margin of the anus are occasionally much dilated, forming a number of hard pendent masses, of a dark bluish color, covered partly by mucous membrane and partly by the integument. These tumors constitute the disease called *external piles*.

Dissection (Fig. 631).—Make an incision through the integument, along the median line, from the base of the scrotum to the anterior extremity of the anus: carry it round the margins of this aperture to its posterior extremity, and continue it backward to about an inch behind the tip of the coccyx. A transverse incision should now be carried across the base of the scrotum, joining the anterior extremity of the preceding; a second, carried in the same direction, should be made in front of the anus; and a third at the posterior extremity of the first incision. These incisions should be sufficiently extensive to enable the dissector to raise the integument from the inner side of the thighs. The flaps of skin corresponding to the ischio-rectal region should now be removed. In dissecting the integument from this region great care is required, otherwise the *Corrugator cutis ani* and *External sphincter* will be removed, as they are intimately adherent to the skin.

The *superficial fascia* is exposed on the removal of the skin: it is very thick, areolar in texture, and contains much fat in its meshes. In it are found ramifying two or three cutaneous branches of the small sciatic nerve: these turn round the inferior border of the *Gluteus maximus* and are distributed to the integument around the anus.

In this region, and connected with the lower end of the rectum, are four muscles: the Corrugator cutis ani; the two Sphincters, External and Internal; and the Levator ani.

These muscles have been already described (see pages 460 and 461).

The *ischio-rectal fossa* is situated between the end of the rectum and the tuberosity of the ischium on each side. It is triangular in shape; its base, directed to the surface of the body, is formed by the integument of the ischio-rectal region; its *apex*, directed upward, corresponds to the point of division of the obturator fascia and the thin membrane given off from it, which covers the outer surface of the Levator ani (ischio-rectal or anal fascia). Its dimensions are about an inch in breadth at the base and about two inches in depth, being deeper behind than in front. It is bounded, *internally*, by the Sphincter ani, Levator ani, and Coccygeus muscles; *externally*, by the tuberosity of the ischium and the obturator fascia, which covers the inner surface of the Obturator internus muscle; *in front*, it is limited by the line of junction of the superficial and deep perineal fasciæ; and *behind*, by the margin of the Gluteus maximus and the great sacro-sciatic ligament. This space is filled with a large mass of adipose tissue, which explains the frequency with which abscesses in the neighborhood of the rectum burrow to a considerable depth.

If the subject has been injected, on placing the finger on the outer wall of this fossa the internal pudic artery, with its accompanying veins and nerve, will be felt about an inch and a half above the margin of the ischiatic tuberosity, but approaching nearer the surface as they pass forward along the inner margin of the pubic arch. These structures are enclosed in a sheath (canal of Alcock) formed by the obturator fascia, the pudic nerve lying below the artery (Fig. 374). Crossing the space transversely, about its centre are the inferior hæmorrhoidal vessels and nerves, branches of the internal pudic; they are distributed to the integument of the anus and to the muscles of the lower end of the rectum. These vessels are occasionally of large size, and may give rise to troublesome hæmorrhage when divided in the operation of lithotomy or of fistula in ano. At the back part of this space may be seen a branch of the fourth sacral nerve, and, at the fore part of the space the superficial perineal vessels and nerves can be seen for a short distance.

THE PERINÆUM IN THE MALE.

The perineal space is of a triangular form; its deep boundaries are limited, laterally, by the rami of the pubic bones and ischia, meeting in front at the pubic arch; behind, by an imaginary transverse line extending between the tuberosities of the ischia. The lateral boundaries are, in the adult, from three inches to three inches and a half in length, and the base from two to three inches and a half in breadth, the average extent of the space being two inches and three-quarters.

The variations in the diameter of this space are of extreme interest in connection with the operation of lithotomy and the extraction of a stone from the cavity of the bladder. In those cases where the tuberosities of the ischia are near together it would be necessary to make the incisions in the lateral operation of lithotomy less oblique than if the tuberosities were widely separated, and the perineal space consequently wider. The perinaeum is subdivided by the median raphe into two equal parts. Of these, the left is the one in which the operation of lithotomy is performed.

In the middle line the perinaeum is convex, and corresponds to the bulb of the urethra. The skin covering it is of a dark color, thin, freely movable upon the subjacent parts, and covered with sharp crisp hairs, which should be removed before the dissection of the part is commenced. In front of the anus a prominent line commences, the *raphe*, continuous in front with the raphe of the scrotum.

Upon removing the skin and superficial structures from this region, in the manner shown in Fig. 631, a plane of fascia will be exposed, covering in the triangular space and stretching across from one ischio-pubic ramus to the other. This is the *deep layer of the superficial fascia* or *fascia of Colles*. It has already

been described (page 462). It is a layer of considerable strength, and encloses and covers a space in which are contained muscles, vessels, and nerves. It is continuous in front with the dartos of the scrotum; on each side it is firmly attached to the margin of the ischio-pubic ramus and to the tuberosity of the ischium; and posteriorly it curves down behind the *Transversus perinæi* muscles to join the lower margin of the deep perineal fascia.

It is between this layer of fascia and the next layer, the superficial layer of the deep perineal fascia, that extravasation of urine most frequently takes place in cases of rupture of the urethra. The superficial layer of the deep perineal fascia (see page 465) is also attached to the ischio-pubic rami, and in front to the subpubic ligament. It is clear, therefore, that when extravasation of fluid takes place between these two layers, it cannot pass backward, because the two layers are continuous with each other around the *Transversus perinæi* muscles; it cannot extend laterally, on account of the connection of both these layers to the rami of the os pubis and ischium; it cannot find its way into the pelvis, because the opening into this cavity is closed by the deep perineal fascia; and therefore, so long as these two layers remain intact, the only direction in which the fluid can make its way is forward into the areolar tissue of the scrotum and penis, and from thence on to the anterior wall of the abdomen.

When the deep layer of the superficial fascia is removed, a space is exposed between this fascia and the deep perineal fascia in which are contained most of

FIG. 631.—Dissection of perinæum and ischio-rectal region.

the branches of the internal pudic artery, with their accompanying veins; the terminal branches of the internal pudic nerve; some of the muscles connected with the penis and urethra;—in the middle line, the *Accelerator urinæ*; on each side, the *Erector penis*; and behind, the *Transversus perinæi*;—the crura of the corpora cavernosa; and the bulb of the corpus spongiosum. Here also is seen the *central tendinous point of the perinæum*. This is a fibrous point in the middle line of the perinæum between the urethra and the rectum, being about half an inch in front of the anus. At this point five muscles converge and are attached—viz. the *External sphincter ani*, the *Acceleratores urinæ*, and the two *Transversi perinæi* muscles—so that by the contraction of these muscles, which extend in opposite directions, it serves as a fixed point of support.

The *Accelerator urinæ*, the *Erector penis*, and the *Transversus perinæi* muscles have been already described (page 463). They form a triangular space, bounded internally by the *Accelerator urinæ*, externally by the *Erector penis*, and behind by the *Transversus perinæi*. The floor of this space is formed by the triangular ligament of the urethra (deep perineal fascia), and running from behind forward in it are the superficial perineal vessels and nerves, and the transverse perineal artery coursing along the posterior boundary of the space on the *Transversus perinæi* muscle. The two terminal branches of the internal pudic artery are also to be seen in this space: the dorsal artery of the penis ascending between the crus and the pubic arch, and the artery to the corpus cavernosum entering the crus immediately after the division of the parent trunk. The perineal nerve and dorsal nerve of the penis, the two terminal branches of the pudic nerve, are

also contained in this space: the perineal, dividing into muscular and cutaneous branches, and the dorsal nerve, accompanying the dorsal artery along the ischio-pubic ramus, and with it piercing the suspensory ligament to be distributed to the penis.

The Accelerator urinæ and Erector penis should now be removed, when the deep perineal fascia will be exposed, stretching across the front part of the outlet of the pelvis. The urethra is seen perforating its centre just behind the bulb, and on each side is the crus penis, connecting the corpus cavernosum with the rami of the ischium and os pubis.

The **deep perineal fascia** (*triangular ligament*), which has already been described (see page 465), consists of two layers, the inferior or superficial layer of which, sometimes called the *anterior layer of the triangular ligament*, is now exposed. It is united to the superior or deep layer behind, but is separated in front by a sub-fascial space, in which are contained certain structures.

The *superficial layer of the deep perineal fascia* consists of a strong fibrous membrane, the fibres of which are disposed transversely, which stretches across

FIG. 632.—The superficial muscles and vessels of the perineum.

from one ischio-pubic ramus to the other and completely fills in the pubic arch: it is attached in front to the subpubic ligament, except just in the centre, where a small interspace is left for the dorsal vein of the penis. In the erect position of the body it is almost horizontal. It is perforated by the urethra in the middle line, and on each side by the ducts of Cowper's glands. It is pierced also by several branches of the internal pudic artery, the dorsal artery of the penis near the apex of the ligament, the artery to the corpus cavernosum more posteriorly, close to the lateral margin of the ligament, and the artery to the bulb in front of the opening for Cowper's duct. The dorsal nerve of the penis also passes through the ligament in company with the artery of the same name. The *crura penis* are exposed, lying superficial to this ligament. They will be seen to be attached by blunt-pointed processes to the rami of the os pubis and ischium, in front of the tuberosities, and, passing forward and inward, joining to form the body of the penis. In the middle line is the bulb and corpus spongiosum, exposed by the removal of the Accelerator urinæ muscle.

If the superficial layer of the deep perineal fascia is detached on either side, the deep perineal interspace will be exposed and the following parts will be seen between it and the deep layer of the fascia: the subpubic ligament in front, close to the symphysis pubis; the dorsal vein of the penis; the membranous portion of the urethra and the Compressor urethræ muscle; Cowper's glands and their ducts; the pudic vessels and the dorsal nerve of the penis; the artery and nerve of the bulb and a plexus of veins.

The *superior or deep layer of the deep perineal fascia* is derived from the obturator fascia or is continuous with it along the pubic arch. Behind, it joins with the superficial layer of the deep perineal fascia and is continuous with the anal fascia. Above it is the recto-vesical fascia, separated from it on each side by the anterior fibres of the Levator ani, but in the median line these two layers of fascia are continuous and form a median septum, in consequence of the recto-vesical fascia dipping down to join the deep layer of the deep perineal fascia. Thus on each

FIG. 633.—Deep perineal fascia. On the left side the anterior layer has been removed.

side of the middle line, beneath this fascia, is a little interspace in which is contained the anterior fibres of the Levator ani (Levator prostatae). It is bounded, below, by the deep layer of the deep perineal fascia; above, by the recto-vesical fascia, and is separated internally from the space on the other side by the median septum. The deep layer of the deep perineal fascia is pierced by the urethra, and is continued backward around the posterior part of the membranous portion of the urethra and the outer surface of the prostate gland.

The **Compressor urethræ** has already been described (page 466). In addition to this muscle and immediately beneath it *circular muscular fibres* surround the membranous portion of the urethra from the bulb in front to the prostate behind, and are continuous with the muscular fibres of the bladder. These fibres are involuntary.

Cowper's glands are situated immediately below the membranous portion of the urethra, close behind the bulb, and below the artery of the bulb.

The **pudic vessels and dorsal nerve of the penis** are placed along the inner margin of the pudic arch (pages 625 and 833).

The **artery of the bulb** passes transversely inward, from the internal pudic along the base of the triangular ligament, between the two layers of fascia.

accompanied by a branch of the pudic nerve (page 823). If the posterior layer of the deep perineal fascia is removed and the crus penis of one side detached from the bone, the under or perineal surface of the Levator ani is brought fully into view. This muscle, with the triangular ligament in front and the Coccygeus and Piriformis behind, closes the outlet of the pelvis.

The Levator ani and Coccygeus muscles have already been described (page 461).

Position of the Viscera at the Outlet of the Pelvis.—Divide the central tendinous part of the perineum, separate the rectum from its connections by dividing the fibres of the Levator ani, which descend upon the sides of the prostate gland, and draw the gut backward toward the coccyx, when the under surface of the prostate gland, the neck and base of the bladder, the vesiculæ seminales, and the vasa deferentia will be exposed.

The **Prostate Gland** is a pale, firm, glandular body which is placed immediately in front of the neck of the bladder around the commencement of the urethra. It is

FIG. 634.—A view of the position of the viscera at the outlet of the pelvis.

placed in the pelvic cavity, behind and below the symphysis pubis, posterior to the deep perineal fascia, and rests upon the rectum, through which it may be distinctly felt, especially when enlarged. In shape and size it resembles a chestnut. Its base is directed backward toward the neck of the bladder. Its apex is directed forward to the deep perineal fascia, which it touches.

Its under surface is smooth, marked by a slight longitudinal furrow, and rests on the rectum, to which it is connected by areolar tissue. Its upper surface is flattened, marked by a slight longitudinal furrow, and placed about three-quarters of an inch below the pubic symphysis. It measures about an inch and a half in its transverse diameter at the base, an inch in its antero-posterior diameter, and three-quarters of an inch in depth. Hence the greatest extent of incision that can be made in it without dividing its substance completely across is obliquely backward and outward. This is the direction in which the incision is made in it in the lateral operation of lithotomy.

Behind the prostate is the posterior surface of the neck and base of the bladder, a small triangular portion of the bladder being seen, bounded, in front, by the prostate gland; behind, by the recto-vesical fold of the peritoneum; on each side, by the vesicula seminalis and the vas deferens. It is separated from direct contact

with the rectum by the recto-vesical fascia. The relation of this portion of the bladder to the rectum is of extreme interest to the surgeon. In cases of retention of urine this portion of the organ is found projecting into the rectum, between three and four inches from the margin of the anus, and may be easily perforated without injury to any important parts: this portion of the bladder is, consequently, occasionally selected for the performance of the operation of tapping the bladder.

Surgical Anatomy.—The student should consider the position of the various parts in reference to the lateral operation of lithotomy. This operation is performed on the left side of the perinæum, as it is most convenient for the right hand of the operator. A staff having been introduced into the bladder, the first incision is commenced midway between the anus and the back of the scrotum (*i. e.* in an ordinary adult perinæum about an inch and a half in front of the anus) a little on the left side of the raphe, and carried obliquely backward and outward to midway between the anus and tuberosity of the ischium. The incision divides the integument and superficial fascia, the inferior hæmorrhoidal vessels and nerves, and the superficial and transverse perineal vessels. If the forefinger of the left hand is thrust upward and forward into the wound, pressing at the same time the rectum inward and backward, the staff may be felt in the membranous portion of the urethra. The finger is fixed upon the staff, and the structures covering it are divided with the point of the knife, which must be directed along the groove toward the bladder, the edge of the knife being turned outward and backward, dividing in its course the membranous portion of the urethra and part of the left lobe of the prostate gland to the extent of about an inch. The knife is then withdrawn, and the forefinger of the left hand passed along the staff into the bladder. The position of the stone having been ascertained, the staff is to be withdrawn, and the forceps is introduced over the finger into the bladder. If the stone is very large, the opposite side of the prostate may be notched before the forceps is introduced: the finger is now withdrawn, and the blades of the forceps opened and made to grasp the stone, which must be extracted by slow and cautious undulating movements.

Parts Divided in the Operation.—The various structures divided in this operation are as follows: the integument, superficial fascia, inferior hæmorrhoidal vessels and nerves, and probably the superficial perineal vessels and nerves, the posterior fibres of the Accelerator urinae, the Transversus perinæi muscle and artery, the deep perineal fascia, the anterior fibres of the Levator ani, part of the Compressor urethrae, the membranous and prostatic portions of the urethra, and part of the prostate gland.

Parts to be Avoided in the Operation.—In making the necessary incisions in the perinæum for the extraction of a calculus the following parts should be avoided: The primary incision should not be made too near the middle line, for fear of wounding the bulb of the corpus spongiosum or the rectum; nor too far externally, otherwise the pudic artery may be implicated as it ascends along the inner border of the pubic arch. If the incisions are carried too far forward, the artery of the bulb may be divided; if carried too far backward, the entire breadth of the prostate and neck of the bladder may be cut through, which allows the urine to become infiltrated behind the pelvic fascia into the loose areolar tissue between the bladder and rectum, instead of escaping externally; diffuse inflammation is consequently set up, and peritonitis, from the close proximity of the recto-vesical peritoneal fold, is the result. If, on the contrary, the prostate is divided in front of the base of the gland, the urine makes its way externally, and there is less danger of infiltration taking place.

During the operation it is of great importance that the finger should be passed into the bladder *before* the staff is removed; if this is neglected, and if the incision made in the prostate and neck of the bladder is too small, great difficulty may be experienced in introducing the finger afterward; and in the child, where the connections of the bladder to the surrounding parts are very loose, the force made in the attempt is sufficient to displace the bladder upward into the abdomen, out of the reach of the operator. Such a proceeding has not unfrequently occurred, producing the most embarrassing results and total failure of the operation.

It is necessary to bear in mind that the arteries in the perinæum occasionally take an abnormal course. Thus the artery of the bulb, when it arises, as sometimes happens, from the pudic opposite the tuber ischii, is liable to be wounded in the operation for lithotomy in its passage forward to the bulb. The accessory pudic may be divided near the posterior border of the prostate gland, if this is completely cut across; and the prostatic veins, especially in people advanced in life, are of large size, and give rise, when divided, to troublesome hæmorrhage.

THE FEMALE PERINÆUM.

The female perinæum presents certain differences from that of the male, in consequence of the whole of the structures which constitute it being perforated in the middle line by the vulvo-vaginal passage.

The superficial fascia, as in the male, consists of two layers, of which the superficial one is continuous with the superficial fascia over the rest of the body, and the deep layer, corresponding to the fascia of Colles in the male, is like it attached to the ischio-pubic ramus, and in front is continued forward through

the labia majora to the inguinal region. It is of less extent than the male, in consequence of being perforated by the aperture of the vulva.

On removing this fascia the muscles of the female perineum, which have already been described (page 466), are exposed. The Sphincter vaginae, corresponding to the Accelerator urinae in the male, consists of an attenuated plane of fibres, forming an orbicular muscle around the orifice of the vagina, instead of being united in a median raphe, as in the male. The Erector clitoridis is proportionately reduced in size, but differs in no other respect, and the Transversus perinaei is similar to the muscle of the same name in the male.

The deep perineal fascia is not so strongly marked as in the male. It transmits the urethra, and is wide, separated in the median line by the aperture of the vagina.

The Compressor Urethrae (*Transversus perinaei profundus*) is the analogue of the Compressor urethrae in the male. It arises from the ischio-pubic ramus, and, passing inward, its anterior fibres blend with the muscle of the opposite side, in front of the urethra; its middle fibres, the most numerous, are inserted into the side of the vagina, and the posterior fibres join the central point of the perineum.

The distribution of the internal pudic artery is the same as in the male (see page 627), and the pudic nerve has also a similar arrangement, the dorsal nerve being, however, very small and supplying the clitoris.

The corpus spongiosum is divided into two lateral halves, which are represented by the *bulbi vestibuli* and *partes intermediales* (see page 1049).

The perineal body fills up the interval between the lower part of the vagina and the rectum. Its base is covered by the skin lying between the anus and

FIG. 635.—A transverse section of the pelvis, showing the pelvic fascia from behind.

vagina on what is called the "perineum." Its anterior surface lies behind the posterior vaginal wall, and its posterior surface lies in front of the anterior rectal wall and the anus. It measures about an inch and a quarter from before backward, and laterally extends from one tuberosity of the ischium to the other. In it are situated the muscles belonging to the external organs of generation. Through its

centre runs the transverse perineal septum, which is of great strength in women, and forms on either side, behind the posterior commissure, a hard, ill-defined body, consisting of connective tissue, with much yellow elastic tissue and interlacing bundles of involuntary muscular fibres, in which the voluntary muscles of the perineum are inserted.

PELVIC FASCIA.

The **Pelvic fascia** (Fig. 635) is a thin membrane which lines the whole of the cavity of the pelvis and is continuous with the transversalis and iliac fasciæ. It is attached to the brim of the pelvis, for a short distance, at the side of the cavity, and to the inner surface of the bone round the attachment of the Obturator internus. At the posterior border of this muscle it is continued backward as a very thin membrane in front of the Piriformis muscle and sacral nerves to the front of the sacrum. In front it follows the attachment of the Obturator internus to the bone, arches beneath the obturator vessels, completing the orifice of the obturator canal, and at the front of the pelvis is attached to the lower part of the symphysis pubis. At the level of a line extending from the lower part of the symphysis pubis to the

FIG. 636.—Side view of the pelvic viscera of the male subject, showing the pelvic and perineal fasciæ.

spine of the ischium is a thickened whitish band; this marks the attachment of the Levator ani muscle to the pelvic fascia, and corresponds to its point of division into two layers, the *obturator* and *recto-vesical*.

The **obturator fascia** descends and covers the Obturator internus muscle. It is a direct continuation of the pelvic fascia below the white line above mentioned, and is attached to the pubic arch and to the margin of the great sacro-sciatic ligament. From its attachment to the rami of the os pubis and ischium a process is given off which is continuous with a similar process from the opposite side, so as to close the front part of the outlet of the pelvis, forming the posterior layer of the triangular ligament. This fascia forms a canal for the pudic vessels and nerve in their passage forward to the perinæum, and gives off a thin membrane

which covers the perineal aspect of the Levator ani muscle (*anal*) fascia.

The **recto-vesical fascia** (*visceral layer of the pelvic* pelvis upon the upper surface of the Levator ani muscle, bladder, and rectum. From the inner surface of the rounded band is continued to the upper surface of the bladder, forming the pubo-prostatic or anterior true ligament. On the side this fascia is connected to the side of the prostate and the vesico-prostatic plexus of veins, and is continued to the bladder, forming the lateral true ligaments of the organ. It invests the vesiculæ seminales, and passes across the rectum, being continuous with the same fascia of the opposite side. Its prolongation is reflected round the surface of the lower part of the Levator ani muscle arising from the point of division of the fascia descending upon and being in contact with the upper surface of the muscle, while the under surface of the thin layer derived from the obturator fascia, called the *ischio-rectal* fascia. In the female the vagina perforates the recto-vesical fascia and its prolongation from it.

LEA BROTHERS & CO.'S

CLASSIFIED CATALOGUE OF

Medical and Surgical Publications.

IN ASKING the attention of the profession to the works advertised in the following pages, the publishers would state that no pains are spared to secure a continuance of the confidence earned for the publications of the house by their careful selection and accuracy and finish of execution.

The printed prices are those at which books can generally be supplied by booksellers throughout the United States, who can readily procure for their customers any works not kept in stock. Where access to bookstores is not convenient, books will be sent by mail by the publishers postpaid on receipt of the printed price, and as the limit of mailable weight has been removed, no difficulty will be experienced in obtaining through the post-office any work in this catalogue. No risks however are assumed either on the money or on the books, and no publications but our own are supplied, so that gentlemen will in most cases find it more convenient to deal with the nearest bookseller.

THE MEDICAL NEWS.

Subscription Price Reduced to
\$4.00 Per Annum.

BY KEEPING closely in touch with the needs of the active practitioner, THE NEWS has achieved a reputation for utility so extensive as to render practicable its reduction in price from five to Four Dollars per annum. It is now by far the cheapest as well as the best large weekly medical journal published in America. Employing all the recognized resources of modern journalism, such as

(Continued on next page.)

2 MEDICAL PERIODICALS—AMERICAN JOURNAL, MEDICAL NEWS.

THE MEDICAL NEWS—Continued.

the cable, telegraph, resident correspondents, special reporters, etc., **THE NEWS** furnishes in the 2 quarto pages of each issue the latest and best information on subjects of importance and value to practitioners in all branches of medicine. The foremost writers, teachers and practitioners of the day furnish original articles, clinical lectures and notes on practical advances; the latest methods in leading hospitals are promptly reported; a condensed summary of progress is gleaned each week from a large exchange list, comprising the best journals at home and abroad; a special department is assigned to abstracts requiring full treatment for proper presentation; editorial articles are secured from writers able to deal instructively with questions of the day; books are carefully reviewed; society proceedings are represented by the pith alone; regular correspondence is furnished by gentlemen in position to know all occurrences of importance in the district surrounding important medical centres, and minor matters of interest are grouped each week under news items. Everything is presented with such brevity as is compatible with clearness, and in the most attractive manner. In a word **THE MEDICAL NEWS** is a crisp, fresh weekly newspaper and as such occupies a well-marked sphere of usefulness, distinct from and complementary to the ideal monthly magazine, **THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES**.

The American Journal of the Medical Sciences

PUBLISHED MONTHLY AT \$4.00 PER ANNUM.

For Commutation Rates see preceding page.

THE AMERICAN JOURNAL will enter with 1894 upon its seventy-fifth year, still maintaining the foremost place among the medical magazines of the world. A vigorous existence during two and a half generations of men amply proves that it has always adapted itself to meet fully the requirements of the time.

Being the medium chosen by the best minds of the profession during this period for the presentation of their ablest papers, **THE AMERICAN JOURNAL** has well earned the praise accorded it by an unquestioned authority—"from this file alone, were all other publications of the press for the last fifty years destroyed, it would be possible to reproduce the great majority of the real contributions of the world to medical science during that period." Original Articles, Reviews and Progress, the three main departments into which the contents of **THE JOURNAL** are divided, will be found to possess still greater interest than in the past. The brightest talent on both sides of the Atlantic is enlisted in its behalf, and no effort will be spared to make **THE JOURNAL** more than ever worthy of its position as the representative of the highest form of medical thought.

The Medical News Visiting List for 1894.

Published in four styles, Weekly (dated for 30 patients); Monthly (undated, for 120 patients per month; Perpetual (undated, for 30 patients weekly per year); and Perpetual (undated, for 60 patients weekly per year). The 60-patient Perpetual consists of 256 pages of assorted blanks. The first three styles contain 32 pages of important data and 176 pages of assorted blanks. Each style is in one wallet-shaped book, leather-bound, with pocket, pencil, rubber, and catheter-scale. Price, each, \$1.25.

For convenience and elegance it is not surpassable.—amount of useful information, especially for emergency and gives good tables of doses and therapeutics.—*Obstetric Gazette.*
This list is all that could be desired. It contains a vast amount of useful information, especially for emergency and gives good tables of doses and therapeutics.—*Practitioner.*

A NEW MEDICAL DICTIONARY. READY VERY SHORTLY.

THE STUDENTS'
Dictionary of Medicine
AND THE ALLIED SCIENCES.

COMPRISING THE PRONUNCIATION, DERIVATION AND FULL EXPLANATION OF MEDICAL TERMS;
TOGETHER WITH MUCH COLLATERAL DESCRIPTIVE MATTER, NUMEROUS TABLES, ETC.

By ALEXANDER DUANE, M.D.,
Assistant Surgeon to the New York Ophthalmic and Aural Institute; Reviser of Medical Terms for
Webster's International Dictionary.

In one Square Octavo Volume of about 600 pages.

THIS handy volume gives succinct but full information concerning every word likely to be met with by students or physicians in the course of medical reading. Especial care has been devoted to making the definitions clear and complete, this main service of a dictionary being expanded to include much descriptive and explanatory matter under headings which would be inadequately represented by a definition, however full. Thus under Diseases are given their causation, symptoms and treatment; under important Organs, an outline of their structure and functions; under each Drug, its action, uses and preparations. Extensive tables of Bacilli, Muscles, Arteries, Veins, etc., are included and the pronunciation and derivation of all words are given in a manner to be readily understood. Each page contains an extraordinary amount of matter set in type of great clearness and beauty. In every detail DUANE'S *Medical Dictionary* has been planned to furnish to the student a standard guide to medical terms on a level with the existing advanced condition of the medical sciences.

The National Medical Dictionary,

INCLUDING ENGLISH, FRENCH, GERMAN, ITALIAN AND LATIN TECHNICAL TERMS USED IN MEDICINE
AND THE COLLATERAL SCIENCES, AND A SERIES OF TABLES OF USEFUL DATA.

By JOHN S. BILLINGS, M.D., LL.D., Edin. and Harv., D.C.L., Oxon.,
Member of the National Academy of Sciences, Surgeon U. S. A., etc.

In Two very Handsome Royal Octavo Volumes containing 1574 Pages, with Two Colored
Plates. Per Volume—cloth, \$6.00; leather, \$7.00; half
Morocco, marbled edges, \$8.50.

For sale by subscription only. Specimen pages on application. Address the Publishers.

Its scope is one which will at once satisfy the student and meet all the requirements of the medical practitioner. The work is remarkable, too, for its fulness. It presents to the English reader a thoroughly scientific mode of acquiring a rich vocabulary and offers an accurate and ready means of reference in consulting works in any of the three modern continental languages which are richest in medical literature. Apart from the boundless stores of information which may be gained by the study of a good dictionary, one is

enabled by the work under notice to read intelligently any technical treatise in any of the four chief modern languages. There cannot be two opinions as to the great value and usefulness of this dictionary as a book of ready reference for all sorts and conditions of medical men. So far as we have been able to see, no subject has been omitted, and in respect of completeness it will be found distinctly superior to any medical lexicon yet published.—*The London Lancet*, April 5, 1890.

Hoblyn's Dictionary of Medicine.

A Dictionary of the Terms Used in Medicine and the Collateral Sciences. By RICHARD D. HOBLYN, M.D. Revised, with numerous additions, by ISAAC HAYS, M.D., late Editor of the American Journal of the Medical Sciences. In one large royal 12mo. volume of 520 double-columned pages. Cloth, \$1.50; leather, \$2.00.

Lea Brothers & Co., Publishers, 706, 708 & 710 Sansom Street, Philadelphia.

NEW (21ST) EDITION, THOROUGHLY REVISED. JUST READY.

DUNGLISON'S DICTIONARY OF MEDICAL SCIENCE.

CONTAINING A FULL EXPLANATION OF THE VARIOUS SUBJECTS AND TERMS OF ANATOMY, PHYSIOLOGY,
MEDICAL CHEMISTRY, PHARMACY, PHARMACOLOGY, THERAPEUTICS, MEDICINE, HYGIENE, DIETETICS,
PATHOLOGY, SURGERY, OPHTHALMOLOGY, OTOTOLOGY, LARYNGOLOGY, DERMATOLOGY, GYNE-
COLOGY, OBSTETRICS, PEDIATRICS, MEDICAL JURISPRUDENCE AND DENTISTRY, ETC., ETC.

By **ROBLEY DUNGLISON, M.D., LL.D.**

Late Professor of Institutes of Medicine in the Jefferson Medical College of Philadelphia.

Edited by **RICHARD J. DUNGLISON, A.M., M.D.**

New (21st) edition.

Thoroughly revised, greatly enlarged and improved, with the
PRONUNCIATION, ACCENTUATION, AND DERIVATION OF THE TERMS

In one magnificent imperial octavo volume of 1200 pages.

Cloth, \$7 00; leather, \$8.00.

THIS great medical dictionary, which has been for more than two generations the standard of the English-speaking race is now, after several years of incessant labor, issued in a thoroughly revised and greatly enlarged and improved edition. The new words and phrases aggregate 44,000, and by themselves would fill a large volume. Space has been gained by the excision of everything obsolete, and the page has been much enlarged, so that while the new edition contains far more matter than its predecessor, the whole is accommodated within a volume convenient for the hand.

The revision has not only covered every word but it has resulted in a number of important new features designed to confer on the work the utmost usefulness, and to make it answer the most advanced demands of the times.

Pronunciation has been introduced throughout by means of a simple and obvious system of phonetic spelling. At a glance the proper sound of a word is clearly indicated and thus a most important desideratum is supplied.

Derivation affords the utmost aid in recollecting the meanings of words, and gives the power of analyzing and understanding those which are unfamiliar. It is here indicated in the simplest manner. Greek words are spelled with English letters, and thus placed at the command of those unfamiliar with the Greek alphabet.

Definitions, the essence of a dictionary, are clear and full, a characteristic in which this work has always been preeminent. In this edition much explanatory and encyclopedic matter has been added, especially upon subjects of practical value. Thus under the various Diseases will be found their symptoms, treatment, etc.; under Drugs their doses and effects, under Poisoning the symptoms, treatment and antidotes, etc., etc. A vast amount of information has been clearly and conveniently condensed into tables in the alphabet.

The typography is thoroughly in keeping with the excellence of the literary material. In a word, both the editor and the publishers have felt that the world-wide reputation of *Dunglison's Dictionary* has rendered it incumbent on them to ensure that in its remodelled and enlarged shape it should be found equal to all that the student and practitioner can expect from such a work.

Lea Brothers & Co., Publishers, 706, 708 & 710 Sansom Street, Philadelphia.

New (Thirteenth) Edition. Ready in a Few Days.

GRAY'S ANATOMY,

IN COLORS OR IN BLACK.

Anatomy, Descriptive and Surgical.

By HENRY GRAY, F.R.S.,

LECTURER ON ANATOMY AT ST. GEORGE'S HOSPITAL, LONDON.

Edited by T. PICKERING PICK, F.R.C.S.,

Surgeon to and Lecturer on Anatomy at St. George's Hospital, London, Examiner in Anatomy, Royal College of Surgeons of England.

A NEW AMERICAN FROM THE THIRTEENTH ENLARGED AND IMPROVED LONDON EDITION.

In one imperial octavo volume of 1100 pages, with 635 large and elaborate engravings on wood.

Price of edition with illustrations in colors (see below): Cloth, \$7.00; leather, \$8.00.

Price of edition with illustrations in black: Cloth, \$6.00; leather, \$7.00.

SINCE 1857 *Gray's Anatomy* has been the standard work used by students of medicine and practitioners in all English-speaking races. So preeminent has it been among the many works on the subject that thirteen editions have been required to meet the demand. This opportunity for frequent revisions has been fully utilized and the work has thus been subjected to the careful scrutiny of many of the most distinguished anatomists of a generation, and thus a degree of completeness and accuracy has been secured which is not attainable in any other way. In no former revision has so much care been exercised as in the present to provide for the student all the assistance that a text-book can furnish.

The engravings have always formed a distinguishing feature of the work, and in the present edition the series has been enriched and rendered complete by the addition of many new ones. The large scale on which the illustrations are drawn and the clearness of the execution render them of unequalled value in affording a grasp of the complex details of the subject. As heretofore the name of each part is printed in the engraving, thus conveying to the eye at once the position, extent and relations of each organ, vessel, muscle, bone or nerve with a clearness impossible when figures on lines of reference are employed. Distinctive colors have been used to give additional prominence to the attachments of muscles, and to the veins, arteries and nerves. For the sake of those who prefer not to pay the slight increase in cost necessitated by the use of colors the volume is published also in black alone.

The illustrations thus constitute a complete and splendid series, which will greatly assist the student in forming a clear idea of Anatomy, and will also serve to refresh the memory of those who may find in the exigencies of practice the necessity of recalling the details of the dissecting-room. Combining, as it does, a complete Atlas of Anatomy with a thorough treatise on systematic, descriptive and applied Anatomy, the work will be found of great service to all physicians who receive students in their offices, relieving both preceptor and pupil of much labor in laying the groundwork of a thorough medical education.

As this work covers a more extended range of subjects than is customary in the ordinary text-books, giving not only the details necessary for the student, but also the application of those details to the practice of medicine and surgery, it furnishes both a guide for the learner and an admirable work of reference for the active practitioner. A few notices of the previous edition are appended.

A work which has had the head of all other text-books on anatomy throughout the civilized world comes to hand in such beauty of execution and accuracy of text and illustration as more than to make good the large promise of the prospectus. It would be indeed difficult to name a feature wherein *Gray* could be mended or bettered, and it needs no prophet to see that the royal work is destined for many years to hold the first place among anatomical text-books. The work is published with black and colored plates. It is a marvel of book-making.—*American Practitioner and News*.

The most popular work on anatomy ever written.—*Journal of the American Medical Association*.

Gray's Anatomy is the most magnificent work upon anatomy which has ever been published in the English or any other language.—*Cincinnati Medical News*.

As the book now goes to the purchaser he is receiving the best work on anatomy that is published in any language.—*Virginia Medical Monthly*.

Gray's standard Anatomy has been and will be for years the text-book for students. The book needs only to be examined to be perfectly understood.—*Medical Press of Western New York*.

Lea Brothers & Co., Publishers, 706, 708 & 710 Sansom Street, Philadelphia.

Human Monstrosities.

By BARTON C. HIRST, M.D.,
Professor of Obstetrics in the University of
Pennsylvania.

and GEORGE A. PIERSOL, M.D.,
Professor of Anatomy and Embryology in the
University of Pennsylvania.

Magnificent folio, containing 220 pages of text, illustrated with 123 engravings and 39 full-page photographic plates from nature. In four parts, price, each, \$5.00. Complete work just ready. Limited edition, for sale by subscription only. Address the Publishers.

We have before us the fourth and last part of the latest and best work on human monstrosities. This completes one of the masterpieces of American medical literature. Typographically and from an artistic standpoint, the work is unexceptionable. In this last and final volume is presented the most complete bibliography of teratological literature extant. No library will be complete without this magnificent work.—*Journal of the American Medical Association*, May 6, 1893.

It will take its place as a standard work on teratology in medical libraries, and it must always retain the honor of being the first of its kind written in the English language.—*The British Medical Journal*, May 27, 1893.

The authors have sought to present in a concise and convenient form a treatise on Teratology which the obstetrician and pathologist can consult for an explanation and classification of the graver anomalies in development occasionally met with in medical practice. So far as we know there has

been hitherto no comprehensive work on the subject in the English language, the literature of the subject in Europe being scattered and not always easy of access. The authors of the work before us have placed the English-speaking profession greatly in their debt by undertaking what must have largely been a labor of love and by producing a work which certainly fills a gap in English medical literature.—*Boston Medical and Surgical Journal*, January 12, 1893.

This work promises to be one for which a place must be found in the library of every anatomist, pathologist, obstetrician, and teratologist. It is the joint production of an obstetrician and an embryologist and histologist, and this fact makes it certain that both the obstetric and anatomical sides of the subject will be fully represented and described. The book promises to be one of the greatest value to the English-speaking medical world.—*Edinburgh Medical Journal*, April, 1892.

Allen's System of Human Anatomy.

A System of Human Anatomy, Including its Medical and Surgical Relations. For the use of Practitioners and Students of Medicine. By HARRISON ALLEN, M.D., Professor of Physiology in the University of Pennsylvania. With an Introductory Section on Histology by E. O. SHAKESPEARE, M.D., Ophthalmologist to the Philadelphia Hospital. Comprising 813 double-columned quarto pages with 380 illustrations on 109 full-page lithographic plates, many of which are in colors, and 241 engravings in the text. In six Sections, each in a portfolio. Price, per Section, \$3.50; also bound in one volume, cloth, \$23.00; half Russia, \$25.00. For sale by subscription only. Address the Publishers.

Holden's Landmarks, Medical and Surgical.

Landmarks, Medical and Surgical. By LUTHER HOLDEN, F.R.C.S., Surgeon to St. Bartholomew's and the Foundling Hospitals, London. Second American from the third and revised English edition, with additions by W. W. KEEN, M.D., Professor of Artistic Anatomy in the Pennsylvania Academy of Fine Arts. In one 12mo. volume of 148 pages. Cloth, \$1.00.

Clarke & Lockwood's Dissector's Manual.

The Dissector's Manual. By W. B. CLARKE, F.R.C.S., and C. B. LOCKWOOD, F.R.C.S. Demonstrators of Anatomy at St. Bartholomew's Hospital Medical School, London. In one pocket-size 12mo. volume of 396 pages, with 49 illustrations. Limp cloth, red edges, \$1.50. See *Students' Series of Manuals*, page 30.

Treves' Surgical Applied Anatomy.

Surgical Applied Anatomy. By FREDERICK TREVES, F.R.C.S., Senior Demonstrator of Anatomy and Assistant Surgeon at the London Hospital. In one pocket-size 12mo. volume of 540 pages, with 61 illustrations. Limp cloth, red edges, \$2.00. See *Students' Series of Manuals*, page 30.

Bellamy's Surgical Anatomy.

The Student's Guide to Surgical Anatomy: Being a Description of the most Important Surgical Regions of the Human Body, and intended as an Introduction to Operative Surgery. By EDWARD BELLAMY, F.R.C.S., Senior Assistant-Surgeon to the Charing-Cross Hospital. In one 12mo. volume of 300 pages, with 50 illustrations. Cloth, \$2.25.

Wilson's Human Anatomy.

A System of Human Anatomy, General and Special. By ERASMUS WILSON, F.R.S. Edited by W. H. GOBRECHT, M.D., Professor of General and Surgical Anatomy in the Medical College of Ohio. In one large and handsome octavo volume of 616 pages, with 397 illustrations. Cloth, \$4.00; leather, \$5.00.

Cleland's Dissector.

A Directory for the Dissection of the Human Body. By JOHN CLELAND, M.D., Professor of Anatomy, Queen's College, Galway. 12mo. 178 pages. Cloth, \$1.25.

HARTSHORNE'S HAND-BOOK OF ANATOMY AND PHYSIOLOGY. Second edition, revised. 12mo., 310 pages, 220 woodcuts. Cloth, \$1.75.

HORNER'S SPECIAL ANATOMY AND HISTOLOGY. Eighth edition. In two octavo volumes of 1097 pages, with 320 woodcuts. Cloth, \$6.00.

Lea Brothers & Co., Publishers, 706 708 & 710 Sansom Street, Philadelphia.

Draper's Medical Physics.

Medical Physics. A Text-book for Students and Practitioners of Medicine. By JOHN C. DRAPER, M.D., LL.D., Professor of Chemistry in the University of the City of New York. In one octavo volume of 734 pages, with 376 woodcuts, mostly original. Cloth, \$4.00.

While all enlightened physicians will agree that a knowledge of physics is desirable for the medical student, only those actually engaged in the teaching of the primary subjects can be fully aware of the difficulties encountered by students who attempt the study of these subjects without a knowledge of either physics or chemistry. These are especially felt by the teacher of physiology.

It is, however, impossible for him to impart a knowledge of the main facts of his subject and establish them by reasons and experimental demonstration, and at the same time undertake to teach *ab initio* the principles of chemistry or physics. Hence the desirability, we may say the necessity, for some such work as the present one.

No man in America was better fitted than Dr. Draper for the task he undertook and he has provided the student and practitioner of medicine with a volume at once readable and thorough. Even to the student who has some knowledge of physics this book is useful, as it shows him its applications to the profession that he has chosen. Dr. Draper, as an old teacher, knew well the difficulties to be encountered in bringing his subject within the grasp of the average student, and that he has succeeded so well proves once more that the man to write for and examine students is the one who has taught and is teaching them. The book is well printed and fully illustrated, and in every way deserves grateful recognition.—*Montreal Med. Jour.*, July, 1890.

Chemistry and Physics. Cloth, \$1.00. See *The Students' Quiz Series*, page 30.

Power's Human Physiology.—Second Edition.

Human Physiology. By HENRY POWER, M.B., F.R.C.S., Examiner in Physiology, Royal College of Surgeons of England. Second edition. In one 12mo. volume of 509 pages, with 68 illustrations. Cloth, \$1.50. See *Students' Series of Manuals*, page 30.

Robertson's Physiological Physics.

Physiological Physics. By J. MCGREGOR ROBERTSON, M.A., M.B., Muirhead Demonstrator of Physiology, University of Glasgow. In one 12mo. volume of 537 pages, with 219 illustrations. Limp cloth, \$2.00. See *Students' Series of Manuals*, page 30.

The title of this work sufficiently explains the nature of its contents. It is designed as a manual for the student of medicine, an auxiliary to his text-book in physiology, and it would be particularly useful as a guide to his laboratory

experiments. It will be found of great value to the practitioner. It is a carefully prepared book of reference, concise and accurate, and as such we heartily recommend it.—*Journal of the American Medical Association*, Dec. 6, 1884.

Dalton on the Circulation of the Blood.

Doctrines of the Circulation of the Blood. A History of Physiological Opinion and Discovery in regard to the Circulation of the Blood. By JOHN C. DALTON, M.D., Professor Emeritus of Physiology in the College of Physicians and Surgeons, New York. In one handsome 12mo. volume of 293 pages. Cloth, \$2.00.

Dr. Dalton's work is the fruit of the deep research of a cultured mind, and to the busy practitioner it cannot fail to be a source of instruction. It will inspire him with a feeling of gratitude and admiration for those plodding workers

of olden times, who laid the foundation of the magnificent temple of medical science as it now stands.—*New Orleans Medical and Surgical Journal*, Aug. 1885.

Bell's Comparative Anatomy and Physiology.

Comparative Anatomy and Physiology. By F. JEFFREY BELL, M.A., Professor of Comparative Anatomy at King's College, London. In one 12mo. volume of 561 pages, with 229 illustrations. Limp cloth, \$2.00. See *Students' Series of Manuals*, page 30.

The manual is preëminently a student's book—clear and simple in language and arrangement. It is well and abundantly illustrated, and is readable and interesting.

On the whole we consider it the best work in existence in the English language to place in the hands of the medical student.—*Bristol Medico-Chirurgical Journal*, March, 1886.

Ellis' Demonstrations of Anatomy.—Eighth Edition.

Demonstrations of Anatomy. Being a Guide to the Knowledge of the Human Body by Dissection. By GEORGE VINER ELLIS, Emeritus Professor of Anatomy in University College, London. From the eighth and revised London edition. In one very handsome octavo volume of 716 pages, with 249 illustrations. Cloth, \$4.25; leather, \$5.25.

Roberts' Compend of Anatomy.

The Compend of Anatomy. For use in the dissecting-room and in preparing for examinations. By JOHN B. ROBERTS, A.M., M.D., Lecturer in Anatomy in the University of Pennsylvania. In one 16mo. volume of 196 pages. Limp cloth, 75 cents.

Wohler's Outlines of Organic Chemistry. Edited by FITTIG. Translated by IRA REMSEN, M.D., Ph.D. In one 12mo. volume of 550 pages. Cloth, \$3.00.

LEHMANN'S MANUAL OF CHEMICAL PHYSIOLOGY. In one octavo volume of 327 pages, with 41 illustrations. Cloth, \$2.25.

CARPENTER'S HUMAN PHYSIOLOGY. Edited by HENRY POWER. In one octavo volume.

CARPENTER'S PRIZE ESSAY ON THE USE AND ABUSE OF ALCOHOLIC LIQUORS IN HEALTH AND DISEASE. With explanations of scientific words. Small 12mo. 178 pages. Cloth, 60 cents.

Lea Brothers & Co., Publishers, 706, 708 & 710 Sansom Street, Philadelphia.

Foster's Physiology.—Fifth Edition.

Text-Book of Physiology. By MICHAEL FOSTER, M.D., F.R.S., Prelector in Physiology and Fellow of Trinity College, Cambridge, England. New (fourth) and enlarged American from the 6th and revised English edition, with notes and additions. In one handsome octavo volume of 1072 pages, with 282 illustrations. Cloth, \$4.50; leather, \$5.50.

There can be no doubt that this text-book continues to lead all others in the English language. Although the work of the American editor in former editions has been by the author largely adopted in a modified form in this revision, much was still left to be done by the editor to render the work fully adapted to the wants of our American students, so that the American edition will undoubtedly continue to supply the market on this side of the Atlantic. The work, owing to its enormous sale, is offered at an extremely low price.—*Medical and Surgical Reporter*, Jan. 9, 1892.

Dr. Foster is unquestionably the leading English-speaking physiologist of to-day. In its original editions this work was intended principally for advanced students, and it was not fully appreciated in America until revised and enlarged

to meet the wants of junior students also. This process of growth under the repeated revision by author and editor has resulted in a volume containing the matter necessary to constitute a complete text and reference book for student and physician. Notwithstanding the enormous sale now presented, the popularity of the work renders possible its publication at an extremely low price, a point at which the American student has greatly the advantage of his English confrere. It is in every respect an excellent and ideal text-book. The author has succeeded in giving a thoroughly practical and entertaining account of the science. The work is admirably and graphically illustrated.—*Southern Practitioner*, Dec. 1891.

Dalton's Physiology.—Seventh Edition.

A Treatise on Human Physiology. Designed for the use of Students and Practitioners of Medicine. By JOHN C. DALTON, M.D., Professor of Physiology in the College of Physicians and Surgeons, New York, etc. Seventh edition, thoroughly revised and rewritten. In one very handsome octavo volume of 722 pages, with 252 beautiful engravings on wood. Cloth, \$5.00; leather, \$6.00.

From the first appearance of the book it has been a favorite, owing as well to the author's renown as an oral teacher as to the charm of simplicity with which, as a writer, he always succeeds in investing even intricate subjects. It must be gratifying to him to observe the frequency with which his work, written for students and practitioners, is quoted by other writers on physiology. This fact attests its value, and, in great measure, its originality. It now needs no such seal of approbation, however, for the thousands who have studied it in its various editions have never

been in any doubt as to its sterling worth.—*N. Y. Medical Journal*, Oct. 1892.

Professor Dalton's well-known and deservedly-appreciated work has long passed the stage at which it could be reviewed in the ordinary sense. The work is eminently one for the medical practitioner, since it treats most fully of those branches of physiology which have a direct bearing on the diagnosis and treatment of disease. The work is one which we can highly recommend to all our readers.—*Dublin Journal of Medical Sciences*, Feb. 1883.

Chapman's Human Physiology.

A Treatise on Human Physiology. By HENRY C. CHAPMAN, M.D., Professor of Institute of Medicine in the Jefferson Medical College of Philadelphia. In one octavo volume of 925 pages, with 605 engravings. Cloth, \$5.50; leather, \$6.50.

Matters which have a practical bearing on the practice of medicine are lucidly expressed; technical matters are given in minute detail; elaborate directions are stated for the guidance of students in the laboratory. In every respect the work fulfils its promise, whether as a complete treatise

for the student or for the physician: for the former it is so complete that he need look no further, and the latter will find entertainment and instruction in an admirable text of reference.—*North Carolina Medical Journal*, Nov. 1887.

Physiology. Cloth, \$1.00. See *The Students' Quiz Series*, page 30.

Schofield's Elementary Physiology.—Just Ready.

Elementary Physiology for Students. By ALFRED T. SCHOFIELD, M.D., Late House Physician London Hospital. In one 12mo. volume of 380 pages, with 227 engravings and 2 colored plates containing 30 figures. Cloth, \$2.00.

This volume is neither more nor less than its title implies. It is most skillfully put together and a vast deal of ground is covered. The language is clear and perspicuous, the

arrangement is natural and consecutive. The illustrations are numerous and well executed. The book deserves to become popular.—*The Medical News*, July 1, 1893.

Frankland & Japp's Inorganic Chemistry.

Inorganic Chemistry. By E. FRANKLAND, D.C.L., F.R.S., Professor of Chemistry in the Normal School of Science, London, and F. R. JAPP, F.I.C., Assistant Professor of Chemistry in the Normal School of Science, London. In one handsome octavo volume of 677 pages, with 51 woodcuts and 2 plates. Cloth, \$3.75; leather, \$4.75.

This work should supersede other works of its class in the medical colleges. It is certainly better adapted than any work upon chemistry with which we are acquainted to impart that clear and full knowledge of the science which students of medicine should have. Physicians who feel

that their chemical knowledge is behind the times would do well to study this work. The descriptions and demonstrations are made so plain that there is no difficulty in understanding them.—*Cincinnati Medical News*, January, 1886.

Clowes' Qualitative Analysis.—Third Edition.

An Elementary Treatise on Practical Chemistry and Qualitative Inorganic Analysis. Specially adapted for use in the Laboratories of Schools and Colleges and by Beginners. By FRANK CLOWES, D.Sc., London, Senior Science-Master at the High School, Newcastle-under-Lyme, etc. Third American from the fourth and revised English edition. In one 12mo. volume of 387 pages, with 55 illustrations. Cloth, \$2.50.

CLASSEN'S ELEMENTARY QUANTITATIVE ANALYSIS. Translated, with notes and additions, by EDGAR F. SMITH, Ph.D., Assistant Professor of Chemistry in the Towne Science

High School, University of Pennsylvania. In one 12mo. volume of 324 pages, with 36 illustrations. Cloth, \$2.00.

Lea Brothers & Co., Publishers, 706, 708 & 710 Sansom Street, Philadelphia.

Simon's Chemistry.—New (4th) Edition. Just Ready.

Manual of Chemistry. A Guide to Lectures and Laboratory work for Beginners in Chemistry. A Text-book specially adapted for Students of Pharmacy and Medicine. By W. SIMON, Ph.D., M.D., Professor of Chemistry and Toxicology Coll. of Phys. and Surg., Baltimore; Professor of Chemistry in the Maryland College of Pharmacy. New (fourth) edition. In one 8vo. volume of 490 pages, with 44 woodcuts and 7 colored plates illustrating 56 of the most important chemical tests. Cloth, \$3.25.

A work which rapidly passes to its fourth edition needs no further proof of having achieved a success. In the present case the claims to favor are obvious. Emanating from an experienced teacher of medical and pharmaceutical students the volume is closely adapted to their needs. This is shown not only by the careful selection and clear presentation of its subject matter, but by the colored plates of reactions, which form a unique feature. Every teacher will appreciate the saving of his own time, and the advantages accruing to the student from a permanent and accurate standard of comparison for tests depending on colors, and frequently upon their changes. To the practitioner, who is likely to be confronted at any time with important pathological or toxicological questions to be answered by the test-tube, the volume will be of the utmost

value. Such it has proved in the past, and the author has accordingly been enabled, through frequent and thorough revisions to keep his work constantly in touch with the progress of its science and the best methods of its presentation.—*Kansas City Medical Index*, May, 1893.

The appearance within a year of another (the fourth) edition of Professor Simon's work indicates that our favorable opinion of the work as already expressed is shared both by teachers and students. The unique feature of representing color-reactions and colored precipitates by artistically-produced illustrations is attractive and cannot fail to become part of an object lesson, so necessary for the successful study of chemistry. It can be said to rank with the best text-books on pharmaceutical and medical chemistry in this country.—*The Medical News*, July 22, 1893.

Fownes' Chemistry.—Twelfth Edition.

A Manual of Elementary Chemistry; Theoretical and Practical. By GEORGE FOWNES, Ph.D. Embodying WATTS' *Physical and Inorganic Chemistry*. From the twelfth English edition. In one large 12mo. volume of 1061 pages, with 168 engravings and a colored plate. Cloth, \$2.75; leather, \$3.25.

Fownes' *Chemistry* has been a standard text-book upon chemistry for many years. Its merits are very fully known by chemists and physicians everywhere in this country and in England. As the science has advanced by the making of new discoveries, the work has been revised so as to keep it abreast of the times. It has steadily maintained its position as a text-book with medical students. In this work are

treated fully: Heat, Light and Electricity, including Magnetism. The influence exerted by these forces in chemical action upon health and disease, etc., is of the most important kind, and should be familiar to every medical practitioner. We can commend the work as one of the very best text-books upon chemistry extant.—*Cincinnati Medical News*, Oct. 1885.

Attfield's Chemistry.—Twelfth Edition.

Chemistry, General, Medical and Pharmaceutical; Including the Chemistry of the U. S. Pharmacopœia. A Manual of the General Principles of the Science, and their application to Medicine and Pharmacy. By JOHN ATTFIELD, M.A., Ph.D., F.I.C., F.R.S., etc., Professor of Practical Chemistry to the Pharmaceutical Society of Great Britain, etc. A new American, from the twelfth English edition, specially revised by the Author for America. In one handsome royal 12mo. volume of 782 pages, with 88 illustrations. Cloth, \$2.75; leather, \$3.25.

Attfield's *Chemistry* is the most popular book among students of medicine and pharmacy. This popularity rests upon real merits. Attfield's work combines in the happiest manner a clear exposition of the theory of chemistry with the practical application of this knowledge to the everyday dealings of the physician and pharmacist. His book is precisely what the title claims for it. The admirable arrangement of the text enables a reader to get a good idea of Chemistry without the aid of experiments, and again it is a good laboratory guide, and finally it contains such a

mass of well-arranged information that it will always serve as a handy book of reference. He does not allow any unutilizable knowledge to slip into his book; his long years of experience have produced a work which is both scientific and practical, and which shuts out everything in the nature of a superfluity, and therein lies the secret of its success. This last edition shows the marks of the latest progress made in chemistry and chemical teaching.—*New Orleans Medical and Surgical Journal*, Nov. 1889.

Chemistry & Physics. Cloth, \$1.00. See *Students' Quiz Series*, page 30.

Bloxam's Chemistry.—Fifth Edition.

Chemistry, Inorganic and Organic. By CHARLES L. BLOXAM, Professor of Chemistry in King's College, London. From the fifth London edition, thoroughly revised and much improved. In one octavo volume of 727 pages, with 292 illustrations. Cloth, \$2.00; leather, \$3.00.

Comment from us on this standard work is almost superfluous. It differs widely in scope and aim from that of Attfield, and in its way is equally beyond criticism. It adopts the most direct methods in stating the principles, hypotheses and facts of the science. Its language is so terse and lucid, and its arrangement of matter so logical in sequence that the student never has occasion to complain

that chemistry is a hard study. Much attention is paid to experimental illustrations of chemical principles and phenomena, and the mode of conducting these experiments. The book maintains the position it has always held as one of the best manuals of general chemistry in the English language.—*Detroit Lancet*, Feb. 1884.

Luff's Manual of Chemistry.—Just Ready.

A Manual of Chemistry. For the use of Students of Medicine. By ARTHUR P. LUFF, M.D., B.Sc., Lecturer on Medical Jurisprudence and Toxicological Chemistry, St. Mary's Hospital Medical School, London. In one 12mo. volume of 522 pages, with 36 engravings. Cloth, \$2.00. See *Students' Series of Manuals*, page 30.

Greene's Medical Chemistry.

A Manual of Medical Chemistry. For the use of Students. By WILLIAM H. GREENE, M.D., Demonstrator of Chemistry in the Medical Department of the University of Pennsylvania. In one 12mo. volume of 310 pages, with 74 illustrations. Cloth, \$1.75.

Leo Brothers & Co., Publishers, 706, 708 & 710 Sansom Street, Philadelphia.

Vaughan & Novy on Ptomaines and Leucomaines.—2d Ed.

Ptomaines, Leucomaines and Bacterial Proteids; or the Chemical Factors in the Causation of Disease. By VICTOR C. VAUGHAN, Ph.D., M.D., Professor of Physiological and Pathological Chemistry, and Associate Professor of Therapeutics and Materia Medica in the University of Michigan, and FREDERICK G. NOVY, M.D., Instructor in Hygiene and Physiological Chemistry in the University of Michigan. New (second) edition. In one 12mo. volume of 359 pages. Cloth, \$2.25.

This book is one that is of the greatest importance, and the modern physician who accepts bacterial pathology cannot have a complete knowledge of this subject unless he has carefully perused it. To the toxicologist the subject is alike of great import, as well as to the hygienist and sanitarian. It contains information which is not easily obtained elsewhere, and which is of a kind that no medical thinker should be without.—*The American Journal of the Medical Sciences*, April, 1892.

This volume brings prominently to view the correct pathology of a host of diseases. Modern chemistry has furnished no more striking evidence of its value than the discovery of these ultimate causes of disease, a step which necessarily

precedes any rational knowledge of cure or prevention. The literature of these subjects, already vast, was before the preparation of this work scattered and unattainable by those who had most need of its help, namely general practitioners. For the student no more important branch of chemistry exists. The early demand for a second edition of a work on so new a department of science argues well for the curriculum of those colleges which have already made it a branch of study and for the growing prominence on the part of the profession to recognize and use the most enlightened methods for the benefit of their patients.—*Southern Practitioner*, Dec. 1891.

Remsen's Theoretical Chemistry.—New (4th) Edition.

Principles of Theoretical Chemistry, with special reference to the Constitution of Chemical Compounds. By IRA REMSEN, M.D., Ph.D., Professor of Chemistry in the Johns Hopkins University, Baltimore. Fourth and thoroughly revised edition. In one royal 12mo. vol. of 325 pages. Cloth, \$2.00.

The principles of theoretical chemistry need to be put very plainly to the student, for unless he gains a clear insight into the laws which govern the constitution of matter his idea of the whole subject is seldom sound, and he will probably lose the full benefit of a practical course. The book gives clear accounts of all theories and modern speculations. We have noticed this book favorably on a previous occasion, since which time four editions have been printed, and it has recently been translated into the German and Italian languages.—*London Lancet*, May 6, 1893.

The fourth edition of Professor Remsen's well-known book comes again, enlarged and revised. Each edition has enhanced its value. We may say without hesitation that it is a standard work on the theory of chemistry, not excelled and scarcely equalled by any other in any language. Its translation into German and Italian speaks for its exalted position and the esteem in which it is held by the most prominent chemists. We claim for this little work a leading place in the chemical literature of this country.—*The American Journal of the Medical Sciences*, July, 1893.

Charles' Physiological and Pathological Chemistry.

The Elements of Physiological and Pathological Chemistry. A Hand-book for Medical Students and Practitioners. Containing a general account of Nutrition, Foods and Digestion, and the Chemistry of the Tissues, Organs, Secretions and Excretions of the Body in Health and in Disease. Together with the methods for preparing or separating their chief constituents, as also for their examination in detail, and an outline syllabus of a practical course of instruction for students. By T. CHARLES, M.D., F.R.S., M.S., formerly Assistant Professor and Demonstrator of Chemistry and Chemical Physics, Queen's College, Belfast. In one handsome octavo volume of 463 pages, with 38 woodcuts and 1 colored plate. Cloth, \$3.50.

Dr. Charles is fully impressed with the importance and practical reach of his subject, and he has treated it in a competent and instructive manner. We cannot recommend a better book than the present. In fact, it fills a gap in medical text-books, and that is a thing which can rarely

be said nowadays. Dr. Charles has devoted much space to the elucidation of urinary mysteries. He does this with much detail, and yet in a practical and intelligible manner. In fact, the author has filled his book with many practical hints.—*Medical Record*, December 20, 1884.

Hoffmann and Powers' Medicinal Analysis.

A Manual of Chemical Analysis, as applied to the Examination of Medicinal Chemicals and their Preparations. Being a Guide for the Determination of their Identity and Quality, and for the Detection of Impurities and Adulterations. For the use of Pharmacists, Physicians, Druggists and Manufacturing Chemists, and Pharmaceutical and Medical Students. By FREDERICK HOFFMANN, A.M., Ph.D., Public Analyst to the State of New York, and FREDERICK B. POWERS, Ph.D., Professor of Analytical Chemistry in the Philadelphia College of Pharmacy. Third edition, entirely rewritten and much enlarged. In one octavo volume of 621 pages, with 179 illustrations. Cloth, \$4.25.

Parrish's Pharmacy.—Fifth Edition.

A Treatise on Pharmacy: Designed as a Text-book for the Student, and as a Guide for the Physician and Pharmacist. With many Formulæ and Prescriptions. By EDWARD PARRISH, late Professor of the Theory of Practice of Pharmacy in the Philadelphia College of Pharmacy. Fifth edition, thoroughly revised, by THOMAS S. WIEGAND, Ph.G. In one handsome octavo volume of 1093 pages, with 256 illustrations. Cloth, \$5.00; leather, \$6.00.

No thorough-going pharmacist will fail to possess himself of so useful a guide to practice, and no physician who properly estimates the value of an accurate knowledge of the remedial agents employed by him in daily practice, so far as their miscibility, compatibility and most effective

methods of combination are concerned, can afford to leave this work out of the list of their works of reference. The country practitioner, who must always be in a measure his own pharmacist, will find it indispensable.—*Lancet*, *Medical News*, March 29, 1884.

Ralfe's Clinical Chemistry.

Clinical Chemistry. By CHARLES H. RALFE, M.D., F.R.C.P., Assistant Physician at the London Hospital. In one pocket-size 12mo. volume of 314 pages, with 16 illustrations. Limp cloth, red edges, \$1.50. See *Students' Series of Manuals*, page 30.

Lea Brothers & Co., Publishers, 706, 708 & 710 Sansom Street, Philadelphia.

New (5th) Edition.—Preparing.

The National Dispensatory.

CONTAINING THE NATURAL HISTORY, CHEMISTRY, PHARMACY, ACTIONS AND USES OF MEDICINES, INCLUDING THOSE RECOGNIZED IN THE PHARMACOPEIAS OF THE UNITED STATES, GREAT BRITAIN AND GERMANY, WITH NUMEROUS REFERENCES TO THE FRENCH CODEX.

By ALFRED STILLÉ, M.D., LL.D., and JOHN M. MAISCH, Phar.D.,
Professor Emeritus of the Theory and Practice of Medicine and of Clinical Medicine in the University of Pennsylvania. *Professor of Materia Medica and Botany in Philadelphia College of Pharmacy, Secretary to the American Pharmaceutical Association.*

New (fifth) edition thoroughly revised, and covering the new United States Pharmacopœia. In one magnificent imperial octavo volume of about 1750 pages, with about 325 elaborate engravings. Preparing.

A few notices of the previous edition are appended.

We think it is a matter for congratulation that the profession of medicine and that of pharmacy have shown such appreciation of this great work as to call for four editions within the comparatively brief period of eight years. The matters with which it deals are of so practical a nature that neither the physician nor the pharmacist can do without the latest text-books on them, especially those that are so accurate and comprehensive as this one. The book is in every way creditable both to the authors and to the publishers.—*The New York Medical Journal*, May 21, 1887.

The authors and publishers have reason to feel proud of

this, the most comprehensive, elaborate and accurate work of the kind ever printed in this country. It is no wonder that it has become the standard authority for both the medical and pharmaceutical professions, and that four editions have been required to supply the constant and increasing demand since its first appearance in 1879. The entire field has been gone over and the various articles revised in accordance with the latest developments regarding the attributes and therapeutical action of drugs. The remedies of recent discovery have received due attention.—*Kansas City Medical Index*, November, 1887.

Maisch's Materia Medica.—New (5th) Edition.

A Manual of Organic Materia Medica; Being a Guide to Materia Medica of the Vegetable and Animal Kingdoms. For the use of Students, Druggists, Pharmacists and Physicians. By JOHN M. MAISCH, Phar.D., Professor of Materia Medica and Botany in the Philadelphia College of Pharmacy. New (fifth) edition, thoroughly revised. In one very handsome 12mo. volume of 544 pages, with 270 engravings. Cloth, \$3.00.

This is an excellent manual of organic materia medica, as are all the works that emanate from the skilful pen of such a successful teacher as John M. Maisch. The book speaks for itself in the most forcible language. In the edition before us, which is the fifth one published within the comparatively short space of eight years (and this is the best proof of the great value of the work and the just favor with which it has been received and accepted), the original contents have been thoroughly revised and much good and new matter has been incorporated. We have nothing but praise for Professor Maisch's work. It presents no weak

point, even for the most severe critic. The book fully sustains the wide and well-earned reputation of its popular author. In the special line of work of which it treats it is fully up to the most recent observations and investigations. After a careful perusal of the book, we do not hesitate to recommend Maisch's *Manual of Organic Materia Medica* as one of the best, if not the best work on the subject thus far published. Its usefulness cannot well be dispensed with, and students, druggists, pharmacists, and physicians should all possess a copy of such a valuable book.—*Medical News*, December 31, 1892.

Edes' Therapeutics and Materia Medica.

A Text-Book of Therapeutics and Materia Medica. Intended for the Use of Student and Practitioners. By ROBERT T. EDES, M.D., Jackson Professor of Clinical Medicine in Harvard University. Octavo, 544 pages. Cloth, \$3.50; leather, \$4.50.

Dr. Edes' book represents better than any older book the practical therapeutics of the present day. The book is a thoroughly practical one. The classification of remedies has reference to their therapeutical action.—*Pharmaceutical Era*, January, 1888.

It possesses all the essentials which we expect in a book

of its kind, such as conciseness, clearness, a judicious classification, and a reasonable degree of dogmatism. All the newest drugs of promise are treated of. The clinical index at the end will be found very useful. We heartily commend the book and congratulate the author on having produced so good a one.—*N. Y. Medical Journal*, Feb., 18, 1888.

Bruce's Materia Medica and Therapeutics.—Fifth Edition.

Materia Medica and Therapeutics. An Introduction to Rational Treatment. By J. MITCHELL BRUCE, M.D., F.R.C.P., Physician and Lecturer on Materia Medica and Therapeutics at Charing-Cross Hospital, London. Fifth edition. In one 12mo. volume of 591 pages. Cloth, \$1.50. See *Students' Series of Manuals*, page 30.

The pharmacology and therapeutics of each drug are given with great fulness, and the indications for its rational employment in the practical treatment of disease are pointed out. The Materia Medica proper contains all that is necessary for a medical student to know at the present

day. The third part of the book contains an outline of general therapeutics, each of the symptoms of the body being taken in turn and the methods of treatment illustrated. A lengthy notice of a book so well known is unnecessary.—*Medical Chronicle*, May, 1891.

Materia Medica and Therapeutics. Cloth, \$1. See *The Students' Quiz Series*, p. 30.

HERMANN'S EXPERIMENTAL PHARMACOLOGY. A Handbook of Methods for Determining the Physiological Action of Drugs. Translated, with the Author's permission, and with extensive additions, by R. M. SMITH, M.D. 12mo., 199 pages, with 32 illustrations. Cloth, \$1.50.

STILLÉ'S THERAPEUTICS AND MATERIA MEDICA. A Systematic Treatise on the Action and Uses of Medicinal Agents, including their Description and History. Fourth edition, revised and enlarged. In two octavo volumes, containing 1346 pages. Cloth, \$10.00; leather, \$12.00.

Lea Brothers & Co., Publishers, 706, 708 & 710 Sansom Street, Philadelphia.

A System of Practical Therapeutics,

BY AMERICAN AND FOREIGN AUTHORS.

Edited by HOBART AMORY HARE, M.D.,

Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia.

In a series of contributions by seventy-eight eminent authorities. In three large octavo volumes of 3544 pages, with 434 illustrations. Price, per volume: Cloth, \$5.00; leather, \$6.00; half Russia, \$7.00. For sale by subscription only. Address the Publishers. Full prospectus free to any address on application.

The various divisions have been elaborated by men selected in view of their special fitness. In every case there is to be found a clear and concise description of the disease under consideration, corresponding with the most recent and well-established views of the subject, embracing appropriate pictorial illustrations where these are necessary. In treating of the employment of remedies and therapeutical measures, the writers have been singularly happy in giving in a definite way the exact methods employed and the results obtained, both by themselves and others, so that one might venture with confidence to use remedies with which he was previously entirely unfamiliar. The practitioner could hardly desire a book on practical therapeutics which he could consult with more interest and profit.—*The North American Practitioner*, September, 1892.

The scope of this work is beyond that of any previous one on the subject. The goal, after all, is the treatment of

disease, and a work which contributes to its successful management is to be looked upon as of vast use to humanity. It cannot be denied that therapeutic resources, whether the treatment be confined to the mere administration of drugs, or allowed its more extended application in the management of disease, have so greatly multiplied within the last few years as to render previous treatises of little value. Herein will be found the great value of Hare's encyclopedic work, which groups together within a single series of volumes the most modern methods known in the management of disease, and especially deals with important subjects comprehensively, which could not be done in a more limited treatise. We cannot commend Hare's *System of Practical Therapeutics* too highly; it stands out first and foremost as a work to be consulted by authors, teachers and physicians throughout the world.—*Buffalo Medical and Surgical Journal*, August, 1892.

Hare's Text-Book of Practical Therapeutics.—New (3d) Ed.

A Text-Book of Practical Therapeutics; With Especial Reference to the Application of Remedial Measures to Disease and their Employment upon a Rational Basis. By HOBART AMORY HARE, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia; Secretary of Convention for Revision of United States Pharmacopoeia of 1890. With special chapters by Drs. G. E. DE SCHWEINITZ, EDWARD MARTIN, J. HOWARD REEVES, and BARSTON C. HIRST. New (third) and revised edition. In one octavo volume of 689 pages. Cloth, \$3.75; leather, \$4.75. Just Ready.

Hare's works on Therapeutics are remarkably well known. As its name would indicate, the book before us is a Text-Book on Practical Therapeutics. Its pretensions are not voluminous nor exhaustive, but they are honest, valuable and practical. The student of other works has often, indeed, very often, longed for less of the abstract materia medica and more of the practical application of drugs to disease. In this work that want is filled. The drugs are arranged alphabetically, which enables one to find any name quickly, and, with the excellent index at the end of the volume, naught is left to be desired in the way of quick reference. Each drug, including all the newer remedies which have been proven to possess true merit, is considered in a rational and scientific manner. This work also presents us with nearly 250 pages of practical therapeutics, as applied to the individual diseases. The subjects are arranged alphabetically. It is in the chapter on *Diseases* that the student finds the rationale of therapeutics. This section

is properly the complement of the former, in which each drug was presented with notes as to its usefulness in numerous diseases, while in the latter each disease is considered very fully from a therapeutical standpoint, giving the applications and special indications of the different remedies in the different phases of that particular affection. It is not a wonder that this work was quickly adopted by many colleges as a text-book and so liberally purchased as to necessitate the publication of a third edition within two years; it is not surprising, but indeed, just what we should reasonably expect. The student will find its pages filled with the choicest of therapeutical lore, systematically arranged and clearly and handsomely presented; the practitioner will appreciate its rationality and its general utility as an elbow consultant. It contains, without question, the best exposition of modern therapeutics of any text-book with which we are acquainted.—*The Chicago Clinical Review*, March, 1893.

Brunton's Therapeutics and Materia Medica.—Third Ed.

A Text-Book of Pharmacology, Therapeutics and Materia Medica. By T. LAUDER BRUNTON, M.D., D.Sc., F.R.S., F.R.C.P., Lecturer on Materia Medica and Therapeutics at St. Bartholomew's Hospital, London, etc. Including the Pharmacy, the Physiological Action and the Therapeutical Uses of Drugs. Adapted to the United States Pharmacopoeia by FRANCIS H. WILLIAMS, M.D., of Harvard University Medical School. Third edition. Octavo, 1305 pages, with 230 illustrations. Leather, \$6.50.

Farquharson's Therapeutics and Materia Medica.—4th Ed.

A Guide to Therapeutics and Materia Medica. By ROBERT FARQUHARSON, M.D., F.R.C.P., LL.D., Lecturer on Materia Medica at St. Mary's Hospital Medical School, London. Fourth American, from the fourth English edition. Enlarged and adapted to the United States Pharmacopoeia, by FRANK WOODBURY, M.D., Professor of Materia Medica and Therapeutics and Clinical Medicine in the Medico-Chirurgical College of Philadelphia. In one handsome 12mo. volume of 581 pages. Cloth, \$2.50.

It may correctly be regarded as the most modern work of its kind. It is concise, yet complete. Containing an account of all remedies that have a place in the British and United States Pharmacopoeias, as well as considering all non-official but important new drugs, it becomes in fact a miniature dispensatory.—*Pacific Medical Journal*, June, 1889.

Farquharson's *Therapeutics and Materia Medica* has struck a happy medium between excessive brevity on the one hand and tedious prolixity on the other. It deals with the entire list of drugs embraced in the *British Pharmacopoeia* in such a way as to give in a satisfactory form the established indi-

cations of each, excluding all irrelevant matter. An especially attractive feature is an arrangement by which the physiological and therapeutical action of various remedies are shown in parallel columns. This aids greatly in fixing attention and facilitates study. The American editor has enlarged the work so as to include all the remedies and preparations in the *United States Pharmacopoeia*. Altogether the book is a most valuable addition to the list of treatises on this most important subject.—*The American Practitioner and News*, November 9, 1889.

Lea Brothers & Co., Publishers, 706, 708 & 710 Sansom Street, Philadelphia.

Flint's Practice of Medicine.—Sixth Edition.

A Treatise on the Principles and Practice of Medicine. Designed for the use of Students and Practitioners of Medicine. By AUSTIN FLINT, M.D., LL.D., Professor of the Principles and Practice of Medicine, and of Clinical Medicine in Bellevue Hospital Medical College, N. Y. Sixth edition, thoroughly revised and rewritten by the Author, assisted by WILLIAM H. WELCH, M.D., Professor of Pathology, Johns Hopkins University, Baltimore, and AUSTIN FLINT, JR., M.D., LL.D., Professor of Physiology, Bellevue Hospital Medical College, New York. In one very handsome octavo volume of 1160 pages, with illustrations. Cloth, \$5.50; leather, \$6.50.

No text-book on the principles and practice of medicine has ever met in this country with such general approval by medical students and practitioners as the work of Professor Flint. In all the medical colleges of the United States it is the favorite work upon Practice; and, as we have stated before in alluding to it, there is no other medical work that can be so generally found in the libraries of physicians. In every State and Territory of this vast country the book that will be most likely to be found in the office of a medical

man, whether in city, town, village, or at some cross-roads, is Flint's *Practice*. We make this statement to a considerable extent from personal observation, and it is the testimony also of others. The work may undoubtedly be regarded as fairly representing the present state of the science of medicine, and as reflecting the views of those who exemplify in their practice the present stage of progress of medical art.—*Cincinnati Medical News*, October, 1886.

Fothergill's Handbook of Treatment.—Third Edition.

The Practitioner's Handbook of Treatment; Or, The Principles of Therapeutics. By J. MILNER FOTHERGILL, M.D., Edinburgh, M.R.C.P., London, Physician to the City of London Hospital for Diseases of the Chest. Third edition. In one 8vo. volume of 661 pages. Cloth, \$3.75; leather, \$4.75.

To have a description of the normal physiological processes of an organ and of the methods of treatment of its morbid conditions brought together in a single chapter, and the relations between the two clearly stated, cannot fail to prove a great convenience to many thoughtful but busy physicians. The practical value of the volume is greatly

increased by the introduction of many prescriptions. That the profession appreciates that the author has undertaken an important work and has accomplished it is shown by the demand for this third edition.—*New York Medical Journal*, June 11, 1887.

The Year-Book of Treatment for 1893.

A Comprehensive and Critical Review for Practitioners of Medicine and Surgery. In one 12mo. vol. of 501 pages. Cloth, \$1.50. * * * For special commutations with periodicals see pages 1 and 2.

The Year-Book of Treatment for 1893 easily holds its advanced place among the many annuals and abstracts forming so marked a feature of modern medical literature. Its pages give a critical and well-arranged review of the best that the year has brought forth in all departments of ther-

apeutics. Among so much that is excellent one can scarcely choose. Commendable features are the Summary of Therapeutics and the Selected List of New Books. There is as usual a good index.—*The Medical News*, May 20, 1893.

The Year-Books of Treatment for 1891 and 1892.

12mos., 485 pages. Cloth, \$1.50 each.

The Year-Books of Treatment for 1886 and 1887.

Similar to above. 12mo., 320-341 pages. Cloth, \$1.25 each.

Hartshorne's Essentials of Practice.—Fifth Edition.

Essentials of the Principles and Practice of Medicine. A Hand-book for Students and Practitioners. By HENRY HARTSHORNE, M.D., LL.D., lately Professor of Hygiene in the University of Pennsylvania. Fifth edition, thoroughly revised and rewritten. In one 12mo. volume of 669 pages, with 144 illustrations. Cloth, \$2.75; half leather, \$3.00.

Within the compass of 600 pages it treats of the history of medicine, general pathology, general symptomatology, and physical diagnosis (including laryngoscope, ophthalmoscope, etc.), general therapeutics, nosology, and special

pathology and practice. There is a wonderful amount of information contained in this work, and it is one of the best of its kind that we have seen.—*Glasgow Medical Journal*, November, 1882.

Practice of Medicine, Including Nervous Diseases.

Cloth, \$1.00. See *Students Quiz Series*, page 30.

BRISTOWE'S PRACTICE OF MEDICINE. Seventh Edition. In one large octavo volume of 1325 pages. Cloth, \$6.50; leather, \$7.50.

REYNOLDS' SYSTEM OF MEDICINE. By J. RUSSELL REYNOLDS, M.D., Professor of the Principles and Practice of Medicine in University College, London. With notes and additions by HENRY HARTSHORNE, A.M., M.D., late Professor of Hygiene in the University of Pennsylvania. Three large octavo volumes, containing 3056 double-columned pages, with 317 illustrations. Price per volume, cloth, \$5.00; sheep, \$6.00; half Russia, raised bands, \$6.50. Per set, cloth, \$15.00; leather, \$18.00; half Russia, \$19.50. Sold only by subscription.

WATSON'S LECTURES ON THE PRINCIPLES AND PRACTICE OF PHYSIC. From the fifth English edition. Edited with additions, and 190 illustrations, by HENRY HARTSHORNE, A.M., M.D., late Professor of Hygiene in the University of Pennsylvania. In two large octavo volumes of 1840 pages. Cloth, \$9.00; leather, \$11.00.

FLINT ON PHTHISIS: ITS MORBID ANATOMY, ETI-

LOGY, SYMPTOMATIC EVENTS AND COMPLICATIONS, FATALITY AND PROGNOSIS, TREATMENT AND PHYSICAL DIAGNOSIS; in a series of Clinical Studies. In one octavo volume of 442 pages. Cloth, \$1.50.

FLINT'S PRACTICAL TREATISE ON THE DIAGNOSIS, PATHOLOGY AND TREATMENT OF DISEASES OF THE HEART. Second revised and enlarged edition. In one octavo volume of 550 pages, with a plate. Cloth, \$4.

FLINT'S ESSAYS ON CONSERVATIVE MEDICINE AND KINDRED TOPICS. In one very handsome royal 12mo. volume of 210 pages. Cloth, \$1.35.

STURGES' INTRODUCTION TO THE STUDY OF CLINICAL MEDICINE. Being a Guide to the Investigation of Disease. In one handsome 12mo. volume of 127 pages. Cloth, \$1.25.

WALSHE ON THE DISEASES OF THE HEART AND GREAT VESSELS. Third American edition. In one octavo volume of 416 pages. Cloth, \$1.00.

HOLLAND'S MEDICAL NOTES AND REFLECTIONS. One octavo volume of 493 pages. Cloth, \$3.50.

Lea Brothers & Co., Publishers, 706, 708 & 710 Sansom Street, Philadelphia.

Lyman's Practice of Medicine.

The Principles and Practice of Medicine. For the Use of Medical Students and Practitioners. By HENRY M. LYMAN, M.D., Professor of the Principles and Practice of Medicine, Rush Medical College, Chicago. In one octavo volume of 925 pages, with 170 illustrations. Cloth, \$4.50; leather, \$5.75.

This is an excellent treatise on the practice of medicine, written by one who is not only familiar with his subject, but who has also learned, through practical experience in teaching, what are the needs of the student, and how to present the facts to his mind in the most readily assimilable form. Each subject is taken up in order, treated clearly but briefly, and dismissed when all has been said that need be said in order to give the reader a clear-cut picture of the disease under discussion. The reader is not confused by having presented to him a variety of different methods of treatment, among which he is left to choose the one most easy of execution, but the author describes the one which is in his judgment the best. This is as it should be. What

the student should be taught is the one most agreed method of treatment. We have spoken of the work more for the student, and this because the author occupies a prominent position as a teacher, but we would not be understood that it is adapted only for students. He will find here each subject presented in its latest aspect, and such theories mentioned as have been generally accepted by the highest authorities. The practical and busy man who wants to ascertain in a short time all the necessary facts concerning the pathology or treatment of any disease will find here a safe and convenient guide. —*Medical Record*, October 22, 1892.

Flint on Auscultation and Percussion.—Fifth Edition.

A Manual of Auscultation and Percussion; Of the Physical Diagnosis of Diseases of the Lungs and Heart, and of Thoracic Aneurism. By AUSTIN FLINT, M.D., LL.D., Professor of the Principles and Practice of Medicine in Bellevue Hospital Medical College, New York. Fifth edition. Edited by JAMES C. WILSON, M.D., Lecturer on Physical Diagnosis in the Jefferson Medical College, Philadelphia. In one handsome royal 12mo. volume of 274 pages, with 12 illustrations. Cloth, \$1.50.

This little book through its various editions has probably done more to advance the science of physical exploration of the chest than any other dissertation upon the subject, and now in its fifth edition it is as nearly perfect as can be. The rapidity with which previous editions were sold shows how the profession appreciated the thoroughness of Pro-

fessor Flint's investigations. For students it is excellent. Its value is shown both in the arrangement of the material and in the clear, concise style of expression. For the practitioner it is a ready manual for reference. —*North American Practitioner*, January, 1891.

Musser's Medical Diagnosis—In Press.

A Practical Treatise on Medical Diagnosis. For the Use of Students and Practitioners. By JOHN H. MUSSER, M.D., Assistant Professor of Clinical Medicine, University of Pennsylvania, Philadelphia. In one octavo volume of about 650 pages, richly illustrated.

Broadbent on the Pulse.

The Pulse. By W. H. BROADBENT, M.D., F.R.C.P., Physician to and Lecturer on Medicine at St. Mary's Hospital, London. In one 12mo. volume of 312 pages. Cloth, \$1.75. See *Series of Clinical Manuals*, page 30.

Pepper's System of Practical Medicine.

BY AMERICAN AUTHORS.

Edited by WILLIAM PEPPER, M.D., LL.D.,

Provost and Professor of the Theory and Practice of Medicine and of Clinical Medicine in the University of Pennsylvania.

The complete work, in five volumes, containing 5573 pages, with 198 illustrations, is now ready. Price per volume, cloth, \$5.00; leather, \$6.00; half Russia, \$7.00. For sale by subscription only.

The feeling of proud satisfaction with which the American profession sees this, its representative system of practical medicine, issued to the medical world, is fully justified by the character of the work. The entire caste of the system is in keeping with the best thoughts of the leaders and followers of our home school of medicine, and the combination of the scientific study of disease and the practical application of exact and experimental knowledge to the treatment of human maladies, makes every one of us share

in the pride that has welcomed Dr. Pepper's labors. Steadfast of the prolixity that wearies the readers of the German school, the articles glean these same fields for all that is valuable. It is the outcome of American brains, and is marked throughout by much of the sturdy independence of thought and originality that is a national characteristic. Yet nowhere is there lack of study of the most advanced views of the day. —*North Carolina Medical Journal*, September, 1888.

Habershon on the Abdomen.

On the Diseases of the Abdomen; Comprising those of the Stomach, and other parts of the Alimentary Canal, Oesophagus, Cecum, Intestines and Peritoneum. By S. O. HABERSHON, M.D., Senior Physician to and late Lecturer on Principles and Practice of Medicine at Guy's Hospital, London. Second American from third enlarged and revised English edition. In one handsome octavo volume of 554 pages, with illustrations. Cloth, \$3.50.

FULLER ON DISEASES OF THE LUNGS AND AIR-PASSAGES. Their Pathology, Physical Diagnosis, Symptoms and Treatment. From the second and revised English edition. In one octavo volume of 475 pages. Cloth, \$3.50.

SLADE ON DIPHThERIA; its Nature and Treatment, with an account of the History of its Prevalence in various Countries. Second and revised edition. In one 12mo. vol., 158 pp. Cloth, \$1.25.

SMITH ON CONSUMPTION; its Early and Remediable Stages. 1 vol. 8vo., 236 pp. Cloth, \$2.25.

LA ROCHE ON PNEUMONIA. 1 vol. 8vo., 430 pages. Cloth, \$3.00.

WILLIAMS ON PULMONARY CONSUMPTION; its Nature, Varieties, and Treatment. With an analysis of over thousand cases to exemplify its duration. In one 8vo. vol. of 303 pp. Cloth, \$2.50.

Lea Brothers & Co., Publishers, 706, 708 & 710 Sansom Street, Philadelphia.

Whitla's Dictionary of Treatment.

A Dictionary of Treatment; or Therapeutic Index, including Medical and Surgical Therapeutics. By WILLIAM WHITLA, M.D., Professor of Materia Medica and Therapeutics in the Queen's College, Belfast. Revised and adapted to the United States Pharmacopœia. In one square, octavo volume of 917 pages. Cloth, \$4.00.

The several diseased conditions are arranged in alphabetical order, and the methods, medical, surgical, dietetic and climatic, by which they may be met, are considered. On every page we find clear and detailed directions for treatment. The book abounds with useful, practical hints and suggestions. The most experienced members of the profession may usefully consult its pages for the purpose

of learning what is really trustworthy in the later therapeutic developments. The *Dictionary* is, in short, the recorded experience of a practical scientific therapist, who has carefully studied diseases and disorders at the bed-side and in the consulting-room, and has earnestly addressed himself to the cure and relief of his patients. *The Glasgow Medical Journal*, April, 1892.

Bartholow on Cholera.—Just Ready.

Cholera: Its Causes, Symptoms, Pathology and Treatment. By ROBERTS BARTHOLOW, M.D., LL.D., Emeritus Professor of Materia Medica, General Therapeutics and Hygiene in the Jefferson Medical College of Philadelphia. In one 12mo. volume of 127 pages, with 9 illustrations. Cloth, \$1.25.

Dr. Bartholow has produced a little book on cholera at once authoritative and complete in its detail. He has shown how all that is absolutely necessary for the practitioner to know about cholera may be compressed into a few pages. Nearly one half the book is given to treatment.—*Journal of the American Medical Association*, July 15, 1893.

We have here a practical book, in small compass, con-

taining the very latest ideas concerning the treatment of cholera, together with the personal experience of the author who has passed through two epidemics of this disease. Historical accounts and long discussions on disputed etiological points are omitted and only that which is of most use to the general practitioner is included.—*The National Medical Review*, August, 1893.

BY THE SAME AUTHOR.

Medical Electricity. A Practical Treatise on the Applications of Electricity to Medicine and Surgery. Third edition. In one octavo volume of 308 pages, with 110 illustrations. Cloth, \$2.50.

Professor Bartholow's practical treatise on the application of electricity to medicine and surgery, having reached a third edition, scarcely requires detailed notice. Originally intended for students and practitioners, it starts by assum-

ing an "entire unacquaintance with the elements of the subject." The work is fitted by its extreme lucidity for the use of busy practitioners who require a guide in practical electro-therapeutics.—*London Lancet*, January 14, 1888.

Yeo's Manual of Medical Treatment.—Just Ready.

A Manual of Medical Treatment or Clinical Therapeutics. By I. BURNEY YEO, M.D., F.R.C.P., Professor of Therapeutics in King's College London. In two 12mo. volumes containing 1275 pages, with illustrations. Complete work, cloth, \$5.50.

In this work disease is studied from the standpoint of treatment, the rational indications for therapeutics being reached through an explanation of the causation and phenomena of disease and of the properties and mode of action of the agencies available for alleviation or cure. The work is rich in selections of formulæ used by well-known physicians.

BY THE SAME AUTHOR.

Food in Health and Disease. In one 12mo. volume of 590 pages. Cloth, \$2.00. See *Series of Clinical Manuals*, page 30.

Dr. Yeo supplies in a compact form nearly all that the practitioner requires to know on the subject of diet. The work is divided into two parts—food in health and food in disease. Dr. Yeo has gathered together from all quarters an immense amount of useful information within a com-

paratively small compass, and he has arranged and digested his materials with skill for the use of the practitioner. We have seldom seen a book which more thoroughly realizes the object for which it was written than this little work of Dr. Yeo.—*British Medical Journal*, February 8, 1890.

Richardson's Preventive Medicine.

Preventive Medicine. By B. W. RICHARDSON, M.D., LL.D., F.R.S., Fellow of the Royal College of Physicians, London. In one 8vo. volume of 729 pages. Cloth, \$4.00; leather, \$5.00.

SCHREIBER ON MASSAGE. A Manual of Treatment by Massage and Methodical Muscle Exercise. By JOSEPH SCHREIBER, M.D. Translated by WALTER MENDELSON, M.D., of New York. In one handsome octavo volume of 274 pages, with 117 fine engravings.

STILLÉ ON CHOLERA: Its Origin, History, Causation, Symptoms, Lesions, Prevention and Treatment. In one handsome 12mo. vol. of 163 pages, with a chart. Cloth, \$1.25.

PAVY'S TREATISE ON THE FUNCTION OF DIGESTION: Its Disorders and their Treatment. From the second London edition. In one octavo volume of 238 pages. Cloth, \$2.00.

BARLOW'S MANUAL OF THE PRACTICE OF MEDICINE. With additions by D. F. CONDIE, M.D. In one octavo volume of 603 pages. Cloth, \$2.50.

CHAMBERS' MANUAL OF DIET AND REGIMEN IN HEALTH AND SICKNESS. In one handsome octavo volume of 302 pages. Cloth, \$2.75.

A TREATISE ON FEVER. By ROBERT D. LYONS, K.C.C. In one octavo volume of 554 pages. Cloth, \$2.25.

LECTURES ON THE STUDY OF FEVER. By A. HED-

SON, M.D., M.R.I.A. In one octavo volume of 308 pages. Cloth, \$2.50.

LA ROCHE ON YELLOW FEVER, in its Historical, Pathological, Etiological and Therapeutical Relations. Two octavo volumes, 1468 pages. Cloth, \$7.00.

TANNER'S MANUAL OF CLINICAL MEDICINE AND PHYSICAL DIAGNOSIS. Third American, from the second London edition. Revised and enlarged by THURERY FOX, M.D. In one 12mo. volume of 362 pages, with illustrations. Cloth, \$1.50.

DAVIS' CLINICAL LECTURES ON VARIOUS IMPORTANT DISEASES. By N. S. DAVIS, M.D. Edited by FRANK H. DAVIS, M.D. Second edition. 12mo., 287 pages. Cloth, \$1.75.

TODD'S CLINICAL LECTURES ON CERTAIN ACUTE DISEASES. In one 8vo. volume of 330 pages. Cloth, \$2.50.

FLINT'S PRACTICAL TREATISE ON THE PHYSICAL EXPLORATION OF THE CHEST AND THE DIAGNOSIS OF DISEASES AFFECTING THE RESPIRATORY ORGANS. Second and revised edition. In one handsome octavo volume of 591 pages. Cloth, \$4.50.

Gray on Nervous and Mental Diseases.—Just Ready.

A Practical Treatise on Nervous and Mental Diseases. By LONDON CARTER GRAY, M.D., Professor of Diseases of the Mind and Nervous System in the New York Polyclinic. In one very handsome octavo volume of 681 pages, with 168 illustrations. Cloth, \$4.50; leather, \$5.50.

It must have been felt by all that the time had come for a new and representative book, and that the author would be both happy and fortunate who would meet this want in the reading and teaching ranks of the profession. This want we can now say has been met. It is evident that the author has drawn, and drawn profitably, from many sources for illustration and enrichment of his text. This gives the book a special value for literary reference. Another merit consists in the originality and distinctness of many of the photographic illustrations. Dr. Gray always speaks with the dogmatism that marks the original observer and that carries conviction. This tone in the book, which is always well modulated and thoroughly under control, will add attractiveness and weight to the author's utterances. Another general characteristic that strikes us most favorably

is the prominence given to the symptoms and the treatment of these diseases. Hence Dr. Gray's book is a very practical one. It does not devote undue space to the microscopic appearances of diseases, nerves and tissues, and the general practitioner and student sees hardly any in a lifetime. Pathology and morbid anatomy, so essential to the expert, are not neglected; but therapeutics, the part of the practitioner, is completely and exhaustively discussed. Dr. Gray's book closes with an important chapter on mental diseases. This is a unique feature for a handbook on nervous diseases, and one, we are sure, that will commend it to many readers. After all, the two volumes of subjects are closely allied, and a concise treatment of both within the same covers is, for many, a desideratum.—*American Journal of the Medical Sciences*, March, 1883.

Ross on Diseases of the Nervous System.

A Hand-book on Diseases of the Nervous System. By JAMES ROSS, M.D., F.R.C.P., LL.D., Senior Assistant Physician to the Manchester Royal Infirmary. In one octavo volume of 172 pages, with 184 illustrations. Cloth, \$4.50; leather, \$5.50.

This admirable work is intended for students of medicine and for such medical men as have no time for lengthy treatises. In the present instance the duty of arranging the vast store of material at the disposal of the author, and of abridging the description of the different aspects of nervous diseases, has been performed with singular skill, and the result is a concise and philosophical guide to the de-

partment of medicine of which it treats. Dr. Ross holds such a high scientific position that any writings which bear his name are naturally expected to have the impress of a powerful intellect. In every part this handbook merits the highest praise, and will no doubt be found of the greatest value to the student as well as to the practitioner.—*Edinburgh Medical Journal*, January, 1887.

Hamilton on Nervous Diseases.—Second Edition.

Nervous Diseases; Their Description and Treatment. By ALLAN McLANE HAMILTON, M.D., Attending Physician at the Hospital for Epileptics and Paralytics, Blackwell's Island, N. Y. Second edition, thoroughly revised and rewritten. In one octavo volume of 598 pages, with 72 illustrations. Cloth, \$4.00.

Savage on Insanity and Allied Neuroses.

Insanity and Allied Neuroses, Practical and Clinical. By GEORGE H. SAVAGE, M.D., Lecturer on Mental Diseases at Guy's Hospital, London. In one 12mo. volume of 551 pages, with 2 illustrations. Cloth, \$2.00. See *Series of Clinical Manuals*, page 30.

Tuke on the Influence of the Mind upon the Body.

Illustrations of the Influence of the Mind Upon the Body in Health and Disease. Designed to elucidate the Action of the Imagination. By DANIEL HACK TUKE, M.D., Joint Author of the *Manual of Psychological Medicine*, etc. New edition, thoroughly revised and rewritten. In one 8vo. volume of 467 pages, with 2 colored plates. Cloth, \$3.00.

Guided by an enlightened deduction, the author has reclaimed for science a most interesting domain in psychology, previously abandoned to charlatans and empirics.

This book, well conceived and well written, must commend itself to every thoughtful understanding.—*New York Medical Journal*, September 6, 1884.

Clouston on Mental Diseases.

Clinical Lectures on Mental Diseases. By THOMAS S. CLOUSTON, M.D., Lecturer on Mental Diseases in the University of Edinburgh. With an Appendix, containing an abstract of the Statutes of the United States and of the Several States and Territories relating to the Custody of the Insane. By CHARLES F. FOLSOM, M.D., Assistant Professor of Mental Diseases, Medical Department of Harvard University. In one octavo volume of 541 pages, with 8 lithographic plates, 4 of which are colored. Cloth, \$4.00.

Dr. Folsom's *Abstract* also separate, in one 8vo. volume of 108 pages. Cloth, \$1.50.

The descriptions of the diseases and cases are simple and practical, but true; and one sees as he reads that they are given by one perfectly familiar from daily observation with the cases and diseases he is speaking of. One feature of the book which commends it highly, and which is not to be found in any other work on mental diseases, are the hints

and descriptions given as to the practical management and care of the cases. We can heartily recommend it to the student and busy general practitioner. Dr. Folsom's work greatly increases the value of Dr. Clouston's book for the American practitioner.—*Archives of Medicine*, June, 1884.

Playfair on Nerve Prostration and Hysteria.

The Systematic Treatment of Nerve Prostration and Hysteria. By W. S. PLAYFAIR, M.D., F.R.C.P. In one 12mo. volume of 97 pages. Cloth, \$1.00.

BLANDFORD ON INSANITY AND ITS TREATMENT. Lectures on the Treatment, Medical and Legal, of Insane Patients. In one very handsome octavo volume.

JONES' CLINICAL OBSERVATIONS ON FUNCTIONAL NERVOUS DISORDERS. Second American edition. In one handsome octavo volume of 340 pages. Cloth, \$3.25.

Lea Brothers & Co., Publishers, 706, 708 & 710 Sansom Street, Philadelphia.

Gibbes' Practical Pathology and Morbid Histology.

Practical Pathology and Morbid Histology. By HENEAGE GIBBES, M.D., Professor of Pathology in the University of Michigan, Medical Department. In one very handsome 8vo. volume of 314 pages, with 60 illustrations, mostly photographic. Cloth, \$2.75.

This is, in part, an expansion of the little work published by the author some years ago, and his acknowledged skill as a practical microscopist will give weight to his instructions. Indeed, in fullness of directions as to the modes of investigating morbid tissues, the book leaves little to be

desired. The work is throughout profusely illustrated with reproductions of micro-photographs. We may say that the practical histologist will gain much useful information from the book.—*The London Lancet*, January 23, 1892.

Abbott's Bacteriology.

The Principles of Bacteriology: a Practical Manual for Students and Physicians. By A. C. ABBOTT, M.D., First Assistant, Laboratory of Hygiene, University of Pennsylvania, Philadelphia. In one 12mo. volume of 259 pages, with 32 illustrations. Cloth, \$2.00.

To a person desiring to learn the technique of bacteriological work, we cannot recommend any work which will be more suitable than the one before us. Dr. Abbott has shown great judgment in the selection and arrangement of his material. The student who follows it closely will be in

a condition to carry forward the work for himself. Medical practitioners generally could read the work with profit, especially the chapters on sterilization and disinfection, and those on tuberculosis and diphtheria in the second part.—*The Canadian Practitioner*, Nov. 1, 1892.

Senn's Surgical Bacteriology.—Second Edition.

Surgical Bacteriology. By NICHOLAS SENN, M.D., Ph.D., Professor of Surgery in Rush Medical College, Chicago. New (second) edition. In one handsome octavo volume of 268 pages, with 13 plates, of which 10 are colored, and 9 engravings. Cloth, \$2.00.

The book is really a systematic collection in the most concise form of such results as are published in current medical literature by the ablest workers in this field of surgical progress; and to these are added the author's own views and the results of his clinical experience and original investigations. The book is valuable to the student, but its chief value lies in the fact that such a compilation makes

it possible for the busy practitioner, whose time for reading is limited and whose sources of information are often few, to become conversant with the most modern and advanced ideas in surgical pathology, which have "laid the foundation for the wonderful achievements of modern surgery."—*Annals of Surgery*, March, 1892.

Green's Pathology and Morbid Anatomy.—Seventh Edition.

Pathology and Morbid Anatomy. By T. HENRY GREEN, M.D., Lecturer on Pathology and Morbid Anatomy at Charing-Cross Hospital Medical School, London. Sixth American from the seventh revised English edition. Octavo volume of 539 pages, with 167 engravings. Cloth, \$2.75.

There is scarcely an intelligent physician anywhere who has not the work in his library, for it is almost an essential. In fact it is better adapted to the wants of general practitioners than any work of the kind with which we are acquainted. The works of German authors upon pathology, which have been translated into English, are too abstruse

for the physician. Dr. Green's work precisely meets his wishes. The fact that it is so generally employed as a text-book by medical students is evidence that we have not spoken too much in its favor.—*Cincinnati Medical News*, October, 1889.

Payne's General Pathology.

A Manual of General Pathology. Designed as an Introduction to the Practice of Medicine. By JOSEPH F. PAYNE, M.D., F.R.C.P., Lecturer on Pathological Anatomy, St. Thomas' Hospital, London. Octavo volume of 524 pages, with 152 illustrations and a colored plate. Cloth, \$3.50.

Knowing, as a teacher and examiner, the exact needs of medical students, the author has in the work before us prepared for their especial use what we do not hesitate to say is the best introduction to general pathology that we have yet examined. A departure which our author has taken is the greater attention paid to the causation of disease, and more especially to the etiological factors in those

diseases now with reasonable certainty ascribed to pathogenic microbes. In this department he has been very full and explicit, not only in a descriptive manner, but in the technique of investigation. The Appendix, giving methods of research, is alone worth the price of the book, several times over, to every student of pathology.—*St. Louis Medical and Surgical Journal*, January, 1889.

Coats' Treatise on Pathology.

A Treatise on Pathology. By JOSEPH COATS, M.D., F.F.P.S., Pathologist to the Glasgow Western Infirmary. In one octavo volume of 829 pages, with 339 illustrations. Cloth, \$5.50; leather, \$6.50.

We are very much pleased with this book, which, for general practitioners and students, comes nearer to our idea of perfection than any we know on this subject, within the same dimensions. The style is exceedingly good, being

plain, concise and practical without being like a dictionary. We have pleasure in recommending it to students, as we think it well adapted for their use.—*Canadian Practitioner*, December, 1893.

Klein's Histology.—Fourth Edition.

Elements of Histology. By E. KLEIN, M.D., F.R.S., Joint Lecturer on General Anatomy and Physiology in the Medical School of St. Bartholomew's Hospital, London. Fourth edition. In one 12mo. volume of 376 pages, with 194 illus. Limp cloth, \$1.75. See *Students' Series of Manuals*, page 30.

The large number of editions through which Dr. Klein's little handbook of histology has run since its first appearance in 1883 is ample evidence that it is appreciated by the medical student and that it supplies a definite want. The

clear and concise manner in which it is written, the absence of debatable matter, of conflicting views, and the convenient size of the book and its moderate price, will account for its undoubted success.—*Medical Chronicle*, Feb., 1890.

Histology, Pathology and Bacteriology. Cloth, \$1. See *Students' Quiz Series*, p. 30.

Lea Brothers & Co., Publishers, 706, 708 & 710 Sansom Street, Philadelphia.

Roberts' Modern Surgery.

The Principles and Practice of Modern Surgery. For the use of Students and Practitioners of Medicine and Surgery. By JOHN B. ROBERTS, M.D., Professor of Anatomy and Surgery in the Philadelphia Polyclinic. Professor of the Principles and Practice of Surgery in the Woman's Medical College of Pennsylvania. Lecturer on Anatomy in the University of Pennsylvania. In one very handsome octavo volume of 780 pages, with 501 illustrations. Cloth, \$4.50; leather, \$5.50.

This work is a very comprehensive manual upon general surgery, and will doubtless meet with a favorable reception by the profession. It has a thoroughly practical character, the subjects are treated with rare judgment, its conclusions are in accord with those of the leading practitioners of the art, and its literature is fully up to all the advanced doc-

trines and methods of practice of the present day. Its general arrangement follows this rule, and the author is so desirous to be concise and practical, is at times almost dogmatic, but this is entirely excusable considering the admirable manner in which he has thus increased the usefulness of his work.—*Medical Record*, January 17, 1891.

Ashhurst's Surgery.—Fifth Edition.

The Principles and Practice of Surgery. By JOHN ASHHURST, JR., M.D., Barton Professor of Surgery and Clinical Surgery in the University of Pennsylvania, Surgeon to the Pennsylvania Hospital, Philadelphia. Fifth edition, enlarged and thoroughly revised. In one octavo volume of 1144 pages, with 642 illustrations. Cloth, \$6.00; leather, \$7.00.

A complete and most excellent work on surgery. It is only necessary to examine it to see at once its excellence and real merit either as text-book for the student or a guide for the general practitioner. It fully considers in detail every surgical injury and disease to which the body is liable, and every advance in surgery worth noting is to be

found in its proper place. It is unquestionably the best and most complete single volume on surgery, in the English language, and cannot but receive that continued appreciation which its merits justly demand.—*Southern Practitioner*, February, 1890.

Druitt's Modern Surgery.—Twelfth Edition.

Manual of Modern Surgery. By ROBERT DRUITT, M.R.C.S. Twelfth edition, thoroughly revised by STANLEY BOYD, M.B., B.S., F.R.C.S. In one 8vo. volume of 965 pages, with 373 illustrations. Cloth, \$4.00; leather, \$5.00.

Druitt's *Surgery* has been an exceedingly popular work in the profession. It is stated that 50,000 copies have been sold in England, while in the United States, ever since its first issue, it has been used as a text-book to a very large extent. During the late war in this country it was so

highly appreciated that a copy was issued by the Government to each surgeon. The present edition, while it has the same features peculiar to the work at first, embodies all recent discoveries in surgery, and is fully up to the times.—*Cincinnati Medical News*, September, 1887.

Gross' System of Surgery.—Sixth Edition.

A System of Surgery. By SAMUEL D. GROSS, M.D., LL.D., Emeritus Professor of Surgery in the Jefferson Medical College of Philadelphia. Sixth edition. In two large imperial octavo volumes containing 2382 pages, illustrated with 1623 engravings. Leather, \$15.00; half Russia, \$16.00.

Surgery. Cloth, \$1.75. See *Students' Quiz Series*, page 30.

Young's Orthopædic Surgery.—In Press.

A Manual of Orthopædic Surgery, for Students and Practitioners. By JAMES K. YOUNG, M.D., Instructor in Orthopædic Surgery, University of Pennsylvania, Philadelphia. In one 12mo. volume of about 400 pages, fully illustrated.

Butlin on the Tongue.

Diseases of the Tongue. By HENRY T. BUTLIN, F.R.C.S., Assistant Surgeon to St. Bartholomew's Hospital, London. In one 12mo. volume of 456 pages, with 8 colored plates and 3 woodcuts. Cloth, \$3.50. See *Series of Clinical Manuals*, page 30.

Gould's Surgical Diagnosis.

Elements of Surgical Diagnosis. By A. PEARCE GOULD, M.S., M.B., F.R.C.S., Assistant Surgeon to Middlesex Hospital, London. In one pocket-size 12mo. volume of 589 pages. Cloth, \$2.00. See *Students' Series of Manuals*, page 30.

Schafer's Histology.—Third Edition.

The Essentials of Histology. By EDWARD A. SCHAFER, M.D., F.R.S., Jodrell Professor of Physiology in University College, London. New (third) edition. In one octavo volume of 311 pages, with 325 illustrations. Cloth, \$3.00.

PEPPER'S SURGICAL PATHOLOGY. In one pocket-size 12mo. volume of 511 pages, with 81 illustrations. Limp cloth, red edges, \$2.00. See *Students' Series of Manuals*, page 30.

PIRRIE'S PRINCIPLES AND PRACTICE OF SURGERY. Edited by JOHN NEILL, M.D. In one octavo volume of 784 pages, with 316 illustrations. Cloth, \$3.75.

GANT'S STUDENT'S SURGERY. By FREDERICK JAMES

GANT, F.R.C.S. Square octavo, 848 pages, 139 engravings. Cloth, \$3.75.

MILLER'S PRACTICE OF SURGERY. Fourth and revised American edition. In one large octavo volume of 604 pages, with 364 illustrations. Cloth, \$3.75.

MILLER'S PRINCIPLES OF SURGERY. Fourth American edition from the third Edinburgh edition. In one octavo volume of 638 pages, with 340 illustrations. Cloth, \$3.75.

Erichsen's Science and Art of Surgery.—Eighth Edition.

The Science and Art of Surgery; Being a Treatise on Surgical Injuries, Diseases and Operations. By JOHN E. ERICHSEN, F.R.S., F.R.C.S., Professor of Surgery in the University College, London, etc. From the eighth and enlarged English edition. In two large octavo volumes of 2316 pages, with 984 engravings on wood. Cloth, \$9.00; leather, \$11.00.

For many years this classic work has been made by preference of teachers the principal text-book on surgery for medical students, while through translations into the leading continental languages it may be said to guide the surgical teachings of the civilized world. No excellence of

the former edition has been dropped and no discovery, device or improvement which has marked the progress of surgery during the last decade has been omitted. The illustrations are many and executed in the highest style of art.—*Louisville Medical News*, February 14, 1885.

Bryant's Practice of Surgery.—Fourth Edition.

The Practice of Surgery. By THOMAS BRYANT, F.R.C.S., Surgeon and Lecturer on Surgery at Guy's Hospital, London. Fourth American from the fourth and revised English edition. In one large imperial octavo volume of 1040 pages, with 727 illustrations. Cloth, \$6.50; leather, \$7.50.

The fourth edition of this work is fully abreast of the times. The author handles his subjects with that degree of judgment and skill which is attained by years of patient toil and varied experience. The present edition is a thorough revision of those which preceded it, with much new matter added. His diction is so graceful and logical, and his explanations are so lucid, as to place the work among

the highest order of text-books for the medical student. Almost every topic in surgery is presented in such a form as to enable the busy practitioner to review any subject in every-day practice in a short time. No time is lost with useless theories or superfluous verbiage. In short, the work is eminently clear, logical and practical.—*Chicago Medical Journal and Examiner*, April, 1886.

Wharton's Minor Surgery and Bandaging.

Minor Surgery and Bandaging. By HENRY R. WHARTON, M.D., Demonstrator of Surgery in the University of Pennsylvania. In one 12mo. volume of 498 pages, with 403 engravings, many being photographic. Cloth, \$3.00.

This new work must take a first rank as soon as examined. Bandaging is well described by words, and the methods are illustrated by photographic drawings, so as to make plain each step taken in the application of bandages of various kinds to different parts of the body and extremities—including the head. The various operations are likewise described and illustrated, so that it would seem easy for the tyro to do the gravest amputation. The various es-

tablished operations are described in detail. Hence this work becomes a most valuable companion-book to any of the more pretentious treatises on surgery, where simply the general advice is given to bandage, amputate, intubate, operate, etc. For the student and young surgeon, it is a very valuable instruction book from which to learn how to do what may be advised, in general terms, to be done.—*Virginia Medical Monthly*, October, 1891.

Treves' Operative Surgery.—Two Volumes.

A Manual of Operative Surgery. By FREDERICK TREVES, F.R.C.S., Surgeon and Lecturer on Anatomy at the London Hospital. In two octavo volumes containing 1550 pages, with 422 engravings. Complete work, cloth, \$9.00; leather, \$11.00.

Mr. Treves in this admirable manual of operative surgery has in each instance practically assumed that operation has been decided upon and has then proceeded to give the various operative methods which may be employed, with a criticism of their comparative value and a detailed and careful description of each particular stage of their performance. Especial attention has been paid to the preparatory treatment of the patient and to the details of the after-treatment of the case, and this is one of the most distinctive among the many excellent features of the book. We declare it the best work on the subject in the English language, and indeed, in many respects, the best in any

language. It cannot fail to be of the greatest use both to practical surgeons and to those general practitioners who, owing to their isolation or to other circumstances, are forced to do much of their own operative work. We recommend the book so strongly for the excellent judgment displayed in the arduous task of selecting from among the thousands of varying procedures those most worthy of description; for the way in which the still more difficult task of choosing among the best of those has been accomplished; and for the simple, clear, straightforward manner in which the information thus gathered from all surgical literature has been conveyed to the reader.—*Annals of Surgery*, March, 1892.

Treves' Student's Hand-Book of Surgical Operations. In one square 12mo. volume of 508 pages, with 94 illustrations. Cloth, \$2.50.

A Manual of Surgery. In Treatises by various Authors, edited by FREDERICK TREVES, F.R.C.S. In three 12mo. volumes, containing 1866 pages, with 213 engravings. Price per set, cloth, \$6.00. See *Students' Series of Manuals*, page 30.

We have here the opinions of thirty-three authors, in an encyclopedic form for easy and ready reference. The three volumes embrace every variety of surgical affections likely to be met with, the paragraphs are short and pithy,

and the salient points and the beginnings of new subjects are always printed in extra-heavy type, so that a person may find whatever information he may be in need of at a moment's glance.—*Cincinnati Lancet-Clinic*, August 21, 1886.

Treves on Intestinal Obstruction. In one 12mo. volume of 522 pages, with 60 illustrations. Limp cloth, blue edges, \$2.00. See *Series of Clinical Manuals*, page 30.

Holmes' System of Surgery.—American Edition.

A System of Surgery; Theoretical and Practical. IN TREATISES BY VARIOUS AUTHORS. Edited by TIMOTHY HOLMES, M.A., Surgeon and Lecturer on Surgery at St. George's Hospital, London. AMERICAN EDITION, THOROUGHLY REVISED AND RE-EDITED BY JOHN H. PACKARD, M.D. Three large octavo volumes of 3137 pages, with 979 illustrations on wood and 13 lithographic plates. Per set, cloth, \$18.00; leather, \$21.00. Subscription only.

Lea Brothers & Co., Publishers, 706, 708 & 710 Sansom Street, Philadelphia.

Smith's Operative Surgery.—Revised Edition

The Principles and Practice of Operative Surgery. By SMITH, M.D., Professor of Clinical Surgery in the University of the City of New York. Second edition. In one very handsome octavo volume of 892 pages, with 1005 illustrations.

This excellent and very valuable book is one of the most satisfactory works on modern operative surgery yet published. The book is a compendium for the modern surgeon. The present edition is much enlarged, and the text has been thoroughly revised, so as to give the most improved methods in aseptic surgery and the latest instruments known for operative work. It can be truly said that, as a handbook for the student, a companion for the surgeon, and even as a book especially engaged in will long hold a most its readers, no matter pages in vain. Its illustrations, and altogether, all combine to make it a most valuable work. *Medical Journal*, May 10, 1892.

Holmes' Treatise on Surgery.—One Volume

A Treatise on Surgery; Its Principles and Practice. By HOLMES, W.H., Surgeon and Lecturer on Surgery at St. George's Hospital, London. Edited by T. PICKERING PICK, F.R.C.S. In one octavo volume of 900 pages. Cloth, \$6.00; leather, \$7.00.

To the younger members of the profession and to others not acquainted with the book and its merits, we take pleasure in recommending it as a surgery complete, thorough, well written, fully illustrated, modern, a work sufficiently voluminous for the surgeon specialist, adequately concise for the general practitioner, and one that are necessary to the collection of the surgeon's present knowledge. *Practitioner*, June 1892.

Hamilton on Fractures and Dislocations.—

A Practical Treatise on Fractures and Dislocations. By HAMILTON, J.D., Surgeon to Bellevue Hospital, New York. New (eighth) edition. By SMITH, M.D., Professor of Clinical Surgery in the University of the City of New York. In one octavo volume of 832 pages, with 507 illustrations. Cloth, \$5.50; leather, \$6.50.

Its numerous editions are convincing proof, if any is needed, of its value and popularity. It is preeminently the authority on fractures and dislocations, and universally quoted as such. In the new edition it has lost none of its former worth. The additions it has received by its recent revision make it a work thoroughly in accordance with modern practice theoretically, mechanically, aseptically. The task of writing a complete treatise on a subject of such magnitude is no easy one. Dr. Smith has aimed to make the present volume the edge of this department. One is at once impressed with its amount of labor its have necessitated. It is impressed with its completeness, and has been accomplished, and has been excellently well. *Booth's Medical Journal*, 26, 1892.

Stimson's Operative Surgery.—Second Edition

A Manual of Operative Surgery. By LEWIS A. STIMSON, M.D., Surgeon in the University of the City of New York. Second edition. 503 pages, with 342 illustrations. Cloth, \$2.50.

The author knows the difficult art of condensation. Thus the manual serves as a work of reference, and at the same time as a handy guide. It teaches what it professes, the steps of operations. In this edition Dr. Stimson has sought to indicate the changes that have been effected in operative methods and procedures by the antiseptic system, and has added some variations in the desire to extend this in British publications. It contains much that is new. *Medical Journal*, January 1892.

Stimson on Fractures and Dislocations.

A Treatise on Fractures and Dislocations. By LEWIS A. STIMSON, M.D. In some octavo volumes. Volume I., FRACTURES, 582 pages, 360 illustrations. 540 pages, with 163 illustrations. Complete work, cloth, \$5.50; separately, cloth, \$3.00; leather, \$4.00.

The appearance of the second volume marks the completion of the author's original plan of preparing a work which should present in the fullest manner all that is known on the cognate subjects of Fractures and Dislocations. The volume on Fractures assumed at once the position of authority on the subject, and its companion on Dislocations will no doubt be similarly received. This volume exhibits the author's original plan of preparing a work and practised by the time. Containing the subjects pertaining to surgery will find it in reference. *Cincinnati Medical Journal*, January 1892.

Pick on Fractures and Dislocations.

Fractures and Dislocations. By T. PICKERING PICK, F.R.C.S., Surgeon at St. George's Hospital, London. In one 12mo. volume of 144 pages. Limp cloth, \$2.00. See *Series of Clinical Manuals*, page 30.

Marsh on the Joints.

Diseases of the Joints. By HOWARD MARSH, F.R.C.S., Surgeon at Bartholomew's Hospital, London. In one 12mo. volume of 468 pages. Limp cloth, \$2.00. See *Series of Clinical Manuals*, page 30.

JUST READY.

A Text-book of Ophthalmology.

By WILLIAM F. NORRIS, M.D., and CHARLES A. OLIVER, M.D.,
Professor of Ophthalmology in the University of Pennsylvania. *Surgeon to Wills Eye Hospital, Philadelphia.*

In one very handsome octavo volume of 641 pages, with 357 engravings and 5 colored plates. Cloth, \$5.00; leather, \$6.00.

The preparation of this magnificent work has engaged its eminent authors during a period exceeding seven years, their effort being to produce a guide for the student and practitioner which should represent the most advanced state of its science in the clearest possible manner. The volume embodies not only the results of large personal experience but also of most extensive acquaintance with the vast and rich literature of its department. By a careful selection of material and the employment of a terse style the Authors have presented an ample working knowledge of their subject in a volume of convenient size. The series of illustrations is singularly rich and is thoroughly in keeping with the literary material which it embellishes. The volume is assured of the foremost position as a text-book and work of reference.

Berry on the Eye.—New Edition. Just Ready.

Diseases of the Eye. A Practical Treatise for Students of Ophthalmology. By GEORGE A. BERRY, M.B., F.R.C.S., Ed., Ophthalmic Surgeon, Edinburgh Royal Infirmary. New (second) edition. In one octavo volume of 750 pages, and 197 illustrations, mostly lithographic. Cloth, \$8.00.

The most notable feature of Berry's book is its wealth of beautifully colored illustrations introduced throughout in immediate connection with the related text. The present edition contains a large number of these that are entirely new, making in all eighty-seven, the finest collection of such illustrations of the normal and pathological appearances of the eye to be found in any work published in the English language. To the practitioner who has not the advantage of a large special clinic in which to become familiar with the rarer forms of eye disease, such illustrations are invaluable.—*Philadelphia Polyclinic*, June 15, 1893.

We are glad to see that a new edition of Mr. Berry's excellent manual has been called for. It has been enlarged to the extent of about fifty pages. The chapters have been rearranged and in many instances considerably augmented. The work is extremely well written, so that it gives the student a fairly complete account of the diseases of the eye he is likely to meet with in practice, and the treatment recommended may be thoroughly relied on as the result of careful observation and of considerable experience.—*The Lancet*, London, April 29, 1893.

Juler's Ophthalmic Science & Practice.—New Ed. Just Ready.

A Handbook of Ophthalmic Science and Practice. By HENRY E. JULER, F.R.C.S., Ophthalmic Surgeon to St. Mary's Hospital, Surgeon to the Royal Westminster Ophthalmic Hospital, London. New (second) edition, revised and enlarged. In one handsome octavo volume of 562 pages, with 201 engravings, 17 colored plates, test-types and color blindness test. Cloth, \$5.50; leather, \$6.50.

It is but comparatively a few years since the profession first had the opportunity of studying and appreciating the exhaustive and scientific work on ophthalmic science and practice from the pen of Mr. Juler. In that work, the second edition of which we now have the pleasure of noting, the author was eminently successful in giving concise descriptions and typical illustrations of all the most important affections of the eye and of its appendages. The second edition of Mr. Juler's work has, we know, been anxiously waited for. The author has made numerous

alterations and additions, alike in the text and in the illustrations, so that the reader is provided in a readable form, and with a conciseness thoroughly compatible with accuracy of description, with all that is most modern on the subject of ophthalmology. We would especially refer our readers to the chapter on the refraction of the eye, a subject of essential importance in the diagnosis and treatment of optical errors. We confidently anticipate a most cordial welcome to this work alike by students and practitioners of medicine.—*The Practitioner*, July, 1893.

Nettleship on the Eye.—Fifth Edition.

Diseases of the Eye. By EDWARD NETTLESHIP, F.R.C.S., Ophthalmic Surgeon at St. Thomas' Hospital, London. Surgeon to the Royal London (Moorfields) Ophthalmic Hospital. Fourth American from the fifth English edition, thoroughly revised. With a Supplement on the Detection of Color Blindness, by WILLIAM THOMSON, M.D., Professor of Ophthalmology in the Jefferson Medical College, Philadelphia. In one 12mo. volume of 500 pages, with 164 illustrations, selections from Snellen's test-types and formulæ, and a colored plate. Cloth, \$2.00.

This is a well-known and a valuable work. It was primarily intended for the use of students, and supplies their needs admirably, but it is as useful for the practitioner, or indeed more so. It does not presuppose the large amount of recondite knowledge to be present which seems

to be assumed in some of our larger works, is not tedious from over-conciseness, and yet covers the more important parts of clinical ophthalmology.—*New York Medical Journal*, Dec. 13, 1890.

Eye, Ear, Throat and Nose. Cloth, \$1.00. See *Students' Quiz Series*, page 30.

Carter & Frost's Ophthalmic Surgery.

Ophthalmic Surgery. By R. BRUDENELL CARTER, F.R.C.S., Lecturer on Ophthalmic Surgery at St. George's Hospital, London, and W. ADAMS FROST, F.R.C.S., Joint Lect. on Oph. Surgery at St. George's Hospital, London. In one 12mo. volume of 559 pages, with 91 woodcuts, color-blindness test, test-types and dots, and appendix of formulæ. Cloth, \$2.25. See *Series of Clinical Manuals*, p. 30.

WELLS ON THE EYE. In one octavo volume.
LAWSON ON INJURIES TO THE EYE, ORBIT AND EYELIDS: Their Immediate and Remote Effects. Octavo of 404 pages, with 92 illustrations. Cloth, \$3.50.

LAURENCE AND MOON'S HANDY BOOK OF OPHTHALMIC SURGERY, for the use of Practitioners. Second edition. In one octavo volume of 227 pages, with 66 illustrations. Cloth, \$2.75.

Lea Brothers & Co., Publishers, 706, 708 & 710 Sansom Street, Philadelphia.

Burnett on the Ear.—Second Edition.

The Ear; Its Anatomy, Physiology and Diseases. A Practical Treatise for the Use of Medical Students and Practitioners. By CHARLES H. BURNETT, A.M., M.D., Professor of Otology in the Philadelphia Polyclinic; President of the American Otological Society. Second edition. In one handsome octavo volume of 580 pages, with 107 illustrations. Cloth, \$4.00; leather, \$5.00.

We note with pleasure the appearance of a second edition of this valuable work. When it first came out it was accepted by the profession as one of the few standard works on modern aural surgery in the English language, and in his second edition Dr. Burnett has fully maintained his reputation, for the book is replete with valuable information and suggestion. The revision has been carefully carried out and much new matter added. Dr. Burnett's work must be regarded as a very valuable contribution to aural surgery, not only on account of its comprehensiveness, but because it contains the results of the careful personal observation and experience of this eminent aural surgeon.—*London Lancet*, February 21, 1885.

We are very glad, after many years' use of the first, to welcome the second edition of this excellent text-book to our shelves. The first 125 pages are devoted to a lucid account of the anatomy, histology and physiology of this most complex organ. The cuts which accompany this part of the work will prove of much use to the student. The second part of the work consists of a clear and terse account of the diseases of the ear and their treatment. In the latter department the rules laid down are eminently practical. We can cordially commend the book to all who wish a text-book on the ear.—*New Orleans Medical and Surgical Journal*, February, 1885.

Field's Manual of Diseases of the Ear.—Just Ready.

A Manual of Diseases of the Ear. By GEORGE P. FIELD, M.R.C.S., Aural Surgeon and Lecturer on Aural Surgery in St. Mary's Hospital School, London. Fourth edition. In one octavo volume of 391 pages, with 73 engravings and 21 colored plates. Cloth, \$3.75.

There can be no question of the need of more perfect knowledge of the pathology of the ear, on the part of general practitioners of medicine. Professor Field has given us a work which makes clear the intricacies of aural anatomy and pathology by the exactness and multiplicity of its illustrations no less than by the explanations of the text. Its popularity is evidenced by the fact that three editions

have already been disposed of, the last numbering 300 copies. The work has, of course, been revised to keep pace with the times.—*The Medical Age*, July 25, 1884.

This book is written by an authority on this subject and may be recommended as a good text-book for the student and a safe and reliable guide for the practitioner.—*Edinburgh Medical Journal*, May, 1885.

Politzer's Text-Book of Diseases of the Ear.—New Ed. In Press.

A Text-Book of Diseases of the Ear and Adjacent Organs. By DR. ADAM POLITZER, Imperial-Royal Professor of Aural Therapeutics in the University of Vienna. Translated into English. In one large octavo volume of about 800 pages, with about 300 engravings.

Browne on the Throat and Nose.—New Ed. Just Ready.

The Throat and Nose and Their Diseases. By LENNOX BROWNE, F.R.C.S., F., Senior Physician to the Central London Throat and Ear Hospital. Fourth and enlarged edition. In one imperial octavo volume of about 750 pages, with 120 illustrations in color, and 235 engravings on wood. Cloth, \$6.50. A few notices of the previous edition are appended.

The beautiful and typical colored plates form a valuable and instructive atlas, the equal of which is not to be found in any modern work treating of these subjects. Mr. Lennox Browne is to be congratulated on having produced the best practical text-book on diseases of the throat and nose extant. We are glad to learn that it is being translated into French and German.—*The Provincial Medical Journal*, August 1, 1890.

As a practical work on the treatment of diseases of the throat and nose this will be found an exceedingly valuable volume. The methods are fully set forth in the text, and

references are made to a very complete and valuable list of formulae. The engravings are upon wood, and all reproductions from the author's pen and ink drawings, by the photo-engraving process. Fifteen colored lithographic plates containing one hundred and twenty illustrations give an added value to the volume. While this work will be of essential service to the specialist it is one that should find a place in the library of every practising physician. It serves admirably to illustrate the progress that is being made in medical literature and especially in the departments which are considered.—*Journal of the American Medical Assn.*, Dec. 6, 1891.

Seiler on the Throat and Nose.—New (4th) Ed. Just Ready.

A Handbook of Diagnosis and Treatment of Diseases of the Throat, Nose and Naso-Pharynx. By CARL SEILER, M.D., Lecturer on Laryngoscopy in the University of Pennsylvania. New (fourth) edition. In one handsome 12mo. volume of 414 pages, with 107 illustrations and 2 colored plates. Cloth, \$2.25.

The mere fact that this work has reached a fourth edition is sufficient evidence that it fills a want long felt by "average general practitioners." As a book of quick, ready reference it has no rival in the field of laryngology, and the directions are usually such as to be readily carried out, even by comparative tyros in the work. The first five chapters deal with the anatomy, physiology and methods of examination of the upper respiratory tract, and are most clear and practical, and are also excellently illustrated. This edition will probably be eagerly welcomed by those for whom it was written, and will be a useful addition to libraries of students and general practitioners.—*Medical News*, July 15, 1893.

The fourth edition of this work is up to the required

standard, which is the highest for one of its scope. It is concise and practical, treating of the commoner diseases of the throat and naso-pharynx, and presenting the scientific features in an intelligible and interesting manner.—*Medical Record*, June 24, 1893.

The fourth edition of Seiler's admirable work should be warmly received by both practitioners and students, as it well deserves. There is no special work of its size on diseases of the throat and nose, that contains more information; yet it is arranged in such a concise, compact form that it makes an exceedingly handy reference book for the busy practitioner as well as a good text-book for the student.—*Pacific Medical Record*, May, 1893.

Diseases of the Eye, Ear, Throat and Nose.

Cloth, \$1.00. See *Students' Quiz Series*, page 39.

BROWNE ON KOCH'S REMEDY IN RELATION TO THROAT CONSUMPTION. In one octavo volume of 121 pages, with 45 illustrations, 4 of which are colored, and 17 charts. Cloth, \$1.50.

Lea Brothers & Co., Publishers, 706, 708 & 710 Sansom Street, Philadelphia.

Roberts on Urinary and Renal Diseases.—Fourth Edition.

A Practical Treatise on Urinary and Renal Diseases, including Urinary Deposits. By SIR WILLIAM ROBERTS, M.D., Lecturer on Medicine in the Manchester School of Medicine, etc. Fourth American from the fourth London edition. In one handsome octavo volume of 609 pages, with 81 illustrations. Cloth, \$3.50.

It may be said to be the best book in print on the subject of which it treats.—*The American Journal of the Medical Sciences*, January, 1886.

The peculiar value and finish of the book are in a measure derived from its resolute maintenance of a clinical and practical character. It is an unrivalled exposition of every-

thing which relates directly or indirectly to the diagnosis, prognosis and treatment of urinary diseases, and possesses a completeness not found elsewhere in our language in its account of the different affections.—*The Manchester Medical Chronicle*, July, 1885.

Purdy on Bright's Disease and Allied Affections.

Bright's Disease and Allied Affections of the Kidneys. By CHARLES W. PURDY, M.D., Professor of Genito-Urinary and Renal Diseases in the Chicago Polyclinic. In one octavo volume of 288 pages, with illustrations. Cloth, \$2.00.

The object of this work is to "furnish a systematic, practical and concise description of the pathology and treatment of the chief organic diseases of the kidney associated with albuminuria, which shall represent the most recent advances in our knowledge on these subjects;" and this definition of the object is a fair description of the book. The work is a useful one, giving in a short space the theo-

ries, facts and treatments, and going more fully into their later developments. On treatment the writer is particularly strong, steering clear of generalities, and seldom omitting what text-books usually do, the unimportant items which are all important to the general practitioner.—*The Manchester Medical Chronicle*, October, 1886.

Gross on the Urinary Organs.

A Practical Treatise on the Diseases, Injuries and Malformations of the Urinary Bladder, the Prostate Gland and the Urethra. By SAMUEL D. GROSS, M.D., LL.D., D.C.L., etc. Third edition, thoroughly revised by SAMUEL W. GROSS, M.D. In one octavo volume of 574 pages, with 170 illustrations. Cloth, \$4.50.

Morris on Surgical Diseases of the Kidney.

Surgical Diseases of the Kidney. By HENRY MORRIS, F.R.C.S., Surgeon to the Middlesex Hospital, London. 12mo. 554 pages, with 40 woodcuts, and 6 colored plates. Limp cloth, \$2.25. See *Series of Clinical Manuals*, page 30.

Thompson on the Urinary Organs.

Lectures on Diseases of the Urinary Organs. By SIR HENRY THOMPSON, Surgeon and Professor of Clinical Surgery to University College Hospital, London. Second American from the third English edition. In one octavo volume of 203 pages, with 25 illustrations. Cloth, \$2.25.

Thompson on the Pathology and Treatment of Stricture of the Urethra and Urinary Fistulæ. From the third English edition. In one octavo volume of 359 pages, with 47 engravings and 3 plates. Cloth, \$3.50.

The American System of Dentistry.

In Treatises by Various Authors. Edited by WILBUR F. LITCH, M.D., D.D.S., Professor of Prosthetic Dentistry, Materia Medica and Therapeutics in the Pennsylvania College of Dental Surgery. In three very handsome octavo volumes containing 3160 pages, with 1863 illustrations and 9 full-page plates. Per volume, cloth, \$6.00; leather, \$7.00; half Morocco, gilt top, \$8.00. For sale by subscription only.

As an encyclopædia of Dentistry it has no superior. It should form a part of every dentist's library, as the information it contains is of the greatest value to all engaged in the practice of dentistry.—*American Journal of Dental Science*, September, 1886.

A grand system, big enough and good enough and handsome enough for a monument (which doubtless it is) to

mark an epoch in the history of dentistry. Dentists will be satisfied with it and proud of it—they must. It is sure to be precisely what the student needs to put him and keep him in the right track, while the profession at large will receive incalculable benefit from it.—*Odontographic Journal*, January, 1887.

Coleman's Dental Surgery.—American Edition.

A Manual of Dental Surgery and Pathology. By ALFRED COLEMAN, L.R.C.P., F.R.C.S., Exam. L.D.S., Senior Dental Surgeon and Lecturer on Dental Surgery at St. Bartholomew's Hospital and the Dental Hospital, London. Thoroughly revised and adapted to the use of American Students, by THOMAS C. STELLWAGEN, M.A., M.D., D.D.S., Professor of Physiology in the Philadelphia Dental College. In one handsome octavo volume of 412 pages, with 331 illustrations. Cloth, \$3.25.

It should be in the possession of every practitioner in this country. The part devoted to first and second dentition and irregularities in the permanent teeth is fully worth the price. In fact, price should not be considered in purchasing

such a work. If the money put into some of our so-called standard text-books could be converted into such publications as this, much good would result.—*Southern Dental Journal*, May, 1882.

BASHAM ON RENAL DISEASES: A Clinical Guide to their Diagnosis and Treatment. In one 12mo. volume of 304 pages, with 21 illustrations. Cloth, \$2.00.

Lea Brothers & Co., Publishers, 706, 708 & 710 Sansom Street, Philadelphia.

Taylor's Clinical Atlas of Venereal and Skin Diseases.

A Clinical Atlas of Venereal and Skin Diseases: Including Diagnosis, Prognosis and Treatment. By ROBERT W. TAYLOR, A.M., M.D., Clinical Professor of Genito-Urinary Diseases in the College of Physicians and Surgeons, New York; Surgeon to the Department of Venereal and Skin Diseases of the New York Hospital; President of the American Dermatological Association. In eight large folio parts, measuring 14 x 18 inches, and comprising 58 beautifully colored plates with 213 figures, and 431 pages of text with 85 engravings. Price, per part, \$2.50. Bound in one volume, half Russia, \$27.00; half Turkey Morocco, \$28.00. *For sale by subscription only.* Specimen plates sent on receipt of 10 cents. A full prospectus sent to any address on application.

It would be hard to use words which would perspicuously enough convey to the reader the great value of this *Clinical Atlas*. This *Atlas* is more complete even than an ordinary course of clinical lectures, for in no one college or hospital course is it at all probable that all of the diseases herein represented would be seen. It is also more serviceable to the majority of students than attendance upon clinical lectures, for most of the students who sit on remote seats in the lecture hall cannot see the subject as well as the office student can examine these true-to-life chromo-lithographs.

Comparing the text to a lecturer, it is more satisfactory in exactness and fulness than he would be likely to be in lecturing over a single case. Indeed, this *Atlas* is invaluable to the general practitioner, for it enables the eye of the physician to make diagnosis of a given case of skin manifestation by comparing the case with the picture in the *Atlas*, where will be found also the text of diagnosis, pathology, and full sections on treatment.—*Virginia Medical Monthly*, December, 1889.

Taylor on Venereal Diseases.—Sixth Edition. Preparing.

The Pathology and Treatment of Venereal Diseases. Including the results of recent investigations upon the subject. By ROBERT W. TAYLOR, A.M., M.D., Clinical Professor of Genito-Urinary Diseases in the College of Physicians and Surgeons, New York, Professor of Venereal and Skin Diseases in the University of Vermont. Being the sixth edition of Bumstead and Taylor. Entirely rewritten by Dr. Taylor. Large octavo volume, about 900 pages, with about 150 engravings, as well as numerous chromo-lithographs. *In active preparation.*

Gross on Impotence, Sterility, etc.—Fourth Edition.

A Practical Treatise on Impotence, Sterility, and Allied Disorders of the Male Sexual Organs. By SAMUEL W. GROSS, A.M., M.D., LL.D., Professor of the Principles of Surgery and of Clinical Surgery in the Jefferson Medical College of Philadelphia. Fourth edition, thoroughly revised by F. R. STURGIS, M.D., Professor of Diseases of the Genito-Urinary Organs and of Venereal Diseases, New York Post-Graduate Medical School. In one octavo volume of 165 pages, with 18 illustrations. Cloth, \$1.50.

Three editions of Professor Gross' valuable book have been exhausted, and still the demand is unsupplied. Dr. Sturgis has revised and added to the previous editions, and the new one appears more complete and more valuable than before. Four important and generally misunderstood subjects are treated—impotence, sterility, spermatorrhea,

and prostaticorrhea. The book is a practical one and in addition to the scientific and very interesting discussions on etiology, symptoms, etc., there are lines of treatment and down that any practitioner can follow and which have met with success in the hands of author and editor.—*Medical Record*, February 25, 1891.

Culver & Hayden's Manual of Venereal Diseases.

A Manual of Venereal Diseases. By EVERETT M. CULVER, M.D., Pathologist and Assistant Attending Surgeon, Manhattan Hospital, New York, and JAMES R. HAYDEN, M.D., Chief of Clinic, Venereal Department, College of Physicians and Surgeons, New York. In one 12mo. volume of 289 pages, with 33 illustrations. Cloth, \$1.75.

This book is a practical treatise, presenting in a condensed form the essential features of our present knowledge of the three venereal diseases, syphilis, chancre and gonorrhea. We have examined this work carefully and have come to the conclusion that it is the most concise, direct and able treatise that has appeared on the subject of ven-

ereal diseases for the general practitioner to adopt as a guide. The general practitioner needs a few simple, concise and clearly presented laws, in the execution of which he cannot fail either to cure or prevent the ravages of the venereal diseases in question and their direful results.—*Buffalo Medical and Surgical Journal*, May, 1892.

Genito-Urinary and Venereal Diseases.

Cloth, \$1.00. See *Students' Quiz Series*, page 30.

Cornil on Syphilis.

Syphilis, its Morbid Anatomy, Diagnosis and Treatment. By V. CORNIL, Professor to the Faculty of Medicine of Paris, and Physician to the Lourcine Hospital. Specially revised by the Author, and translated with notes and additions by J. HENRY C. SIMES, M.D., Demonstrator of Pathological Histology in the University of Pennsylvania, and J. WILLIAM WHITE, M.D., Lecturer on Venereal Diseases, University of Pennsylvania. In one handsome octavo volume of 461 pages, with 84 very beautiful illustrations. Cloth, \$3.75.

Hutchinson on Syphilis.

Syphilis. By JONATHAN HUTCHINSON, F.R.S., F.R.C.S., Consulting Surgeon to the London Hospital. In one 12mo. volume of 542 pages, with 8 chromo-lithographs. Cloth, \$2.25. See *Series of Clinical Manuals*, page 30.

HILL ON SYPHILIS AND LOCAL CONTAGIOUS DISORDERS. In one octavo volume of 479 pages. Cloth, \$5.25.
LEE'S LECTURES ON SYPHILIS AND SOME FORMS

OF LOCAL DISEASE AFFECTING THE ORGANS OF GENERATION. In one octavo volume of 246 pages. Cloth, \$2.25.

Lea Brothers & Co., Publishers, 706, 708 & 710 Sansom Street, Philadelphia.

Hyde on the Skin.—Second Edition.

A Practical Treatise on Diseases of the Skin. For the use of Students and Practitioners. By J. NEVINS HYDE, A.M., M.D., Professor of Dermatology and Venereal Diseases in Rush Medical College, Chicago. Second edition. In one octavo volume of 676 pages, with 2 colored plates and 85 illustrations. Cloth, \$4.50; leather, \$5.50.

We can heartily recommend it, not only as an admirable text-book for teacher and student, but in its clear and comprehensive rules for diagnosis, its sound and independent doctrines in pathology, and its minute and judicious directions for the treatment of disease, as a most satisfactory and complete practical guide for the physician.—*The American Journal of the Medical Sciences*, July, 1888.

In this volume the author has supplied the student with a work of standard value. While thorough and comprehensive in the description of disease, it is especially helpful in the matter of treatment. In this regard it leaves nothing

to the presumed knowledge of the reader, but enters thoroughly into the most minute descriptions, so that one is not only told what should be done under given conditions, but how to do it as well. Care has been taken also to render the nomenclature as clear and unconfusing as the present state of dermatology will admit. The book is one we can heartily recommend as a valuable and creditable addition to American dermatological literature, and a reliable guide to students and practitioners in the requirements of the circumstances of both.—*The American Practitioner and News*, September 29, 1888.

Jackson's Ready-Reference Handbook of Skin Diseases.

The Ready-Reference Handbook of Diseases of the Skin. By GEORGE THOMAS JACKSON, M.D., Professor of Dermatology, Woman's Medical College of the New York Infirmary. In one 12mo. volume of 544 pages, with 50 illustrations and a colored plate. Cloth, \$2.75.

Intended to serve as a reference book for the general practitioner, "no attempt has been made to discuss debatable questions," and "hence pathology and etiology do not receive as full consideration as symptomatology, diagnosis and treatment." The alphabetical arrangement of diseases, so universal now in books of this class, has been followed by Dr. Jackson, and he has inserted so many synonyms and titles from foreign languages, that the book may be turned to even by the specialist in skin diseases as a convenient

dictionary of dermatological nomenclature. After a short and condensed account of the anatomy and physiology of the skin, the author presents a few notes of common and practical importance on diagnosis and therapeutics, which are followed by his well-known and graphic dermatological "Don'ts." Part II. treats in alphabetical order of the diseases of the skin and their management. This book seems to us the best of its class that has yet appeared.—*Boston Medical and Surgical Journal*, May 18, 1893.

Pye-Smith on Diseases of the Skin.—Just Ready.

A Handbook of Diseases of the Skin. By P. H. PYE-SMITH, M.D., F.R.S., Physician to Guy's Hospital, London. Octavo, 407 pages, with 26 illus., 18 of which are colored. Cloth, \$2.00.

The book is an excellent one, and we commend it to all interested in the subject. It is written by one entirely familiar with skin diseases, both from the stand-point of the specialist and the general practitioner. It is written in an easy and attractive style, showing familiarity with the whole field of general medicine as well as the particular diseases described, which is in striking contrast to the contents of the average handbook, from which, as a rule, the reader learns but little. Dr. Pye-Smith is favorably known as one of the eminent physicians at Guy's Hospital, and we have no hesitation in saying that he has written an original and valuable handbook of skin diseases, sound and practical in all its bearings.—*International Med. Magazine*, July, 1893.

It is a plain, practical treatise on dermatology, written for the student and general practitioner by a general practitioner of broad experience in the special subject of which he writes. By grouping the various diseases in as easy and natural a manner as possible, and dropping many of the old, confusing terms, he simplifies the nomenclature and succeeds in removing much of the difficulty that lies in the way of its study. After reviewing the recent advances made in this department of medicine, he pays a merited compliment to the "important contributions made by the newest school of dermatology, that of America."—*Pittsburg Medical Record*, June, 1893.

Hardaway's Manual of Skin Diseases.

Manual of Skin Diseases. With Special Reference to Diagnosis and Treatment. For the Use of Students and General Practitioners. By W. A. HARDAWAY, M.D., Professor of Skin Diseases in the Missouri Medical College. In one 12mo. volume of 440 pages. Cloth, \$3.00.

Dr. Hardaway's large experience as a teacher and writer has admirably fitted him for the difficult task of preparing a book which, while sufficiently elementary for the student, is yet sufficiently thorough and comprehensive to serve as a book of reference for the general practitioner. It embraces all essential points connected with the diagnosis and treatment of diseases of the skin, and we have no hesitation in commending it as the best manual that has yet appeared in this department of medicine.—*Journal of Cutaneous and Genito-Urinary Diseases*.

This little manual is divided into three parts, the first portion being devoted to a general introduction on Symptomatology, Etiology, Diagnosis and Treatment, which is brief, practically complete and clearly stated. The second part considers the clinical characters of the various skin affections in a most satisfactory manner, special stress being placed upon diagnosis and treatment. It concludes with an appendix of special formulae, selected by the author, and a diet table.—*Buffalo Medical and Surgical Journal*, April 1, 1893.

Jamieson on Diseases of the Skin.—Third Edition.

Diseases of the Skin. A Manual for Students and Practitioners. By W. ALLAN JAMIESON, M.D., Lecturer on Diseases of the Skin, School of Medicine, Edinburgh. Third edition, revised and enlarged. In one octavo volume of 656 pages, with woodcut and 9 double-page chromo-lithographic illustrations. Cloth, \$6.00.

The first edition of this work appeared in 1888, and the following year a second. The scope of the work is essentially clinical, little reference being made to pathology or disputed theories. Almost every subject is followed by illustrative cases taken from the author's practice, and the reader is constantly reminded that he has before him a

record of personal experience. The pages are filled with interest to all those occupied with skin diseases. The general practitioner will find the book of great value in matters of diagnosis and treatment. The latter is quite up to date, and the formulae have been selected with care.—*Medical Record*, April 9, 1892.

Diseases of the Skin. Cloth, \$1.00. See *Students' Quiz Series*, page 30.

FOX'S EPITOME OF SKIN DISEASES. WITH FORMULÆ. Third edition, revised and enlarged. In one 12mo. volume of 238 pages. Cloth, \$1.25.

HILLIER'S HANDBOOK OF SKIN DISEASES; for Students and Practitioners. Second American edition.

In one 12mo. volume of 353 pages, with plates. Cloth, \$2.25.

WILSON'S STUDENT'S BOOK OF CUTANEOUS MEDICINE AND DISEASES OF THE SKIN. In one handsome small octavo volume of 535 pages. Cloth, \$3.50.

Lea Brothers & Co., Publishers, 706, 708 & 710 Sansom Street, Philadelphia.

THE AMERICAN SYSTEMS OF Gynecology and Obstetrics

IN TREATISES BY VARIOUS AUTHORS.

Gynecology edited by

MATTHEW D. MANN, A.M., M.D., and

Obstetrics edited by

BARTON COOKE HIRST, M.D.,

Professor of Obstetrics and Gynecology in the Medical
Department of the University of Buffalo.

Professor of Obstetrics in the University of
Pennsylvania, Philadelphia.

In four very handsome octavo volumes, containing 3612 pages, 1092 engravings and 8 plates. Complete work now ready. Per volume: Cloth, \$5.00; leather, \$6.00; half Russia, \$7.00. For sale by subscription only. Address the Publishers. Full descriptive circular free on application.

These volumes are the contributions of the most eminent gentlemen of this country in these departments of the profession. Each contributor presents a monograph upon his special topic, so that everything in the way of history, theory, methods and results is presented to our fullest need. As a work of general reference, it will be found remarkably full and instructive in every direction of inquiry.—*The Obstetric Gazette*, September, 1889.

One is at a loss to know what to say of this volume, for fear that just and merited praise may be mistaken for flattery. The papers of Drs. Engelmann, Martin, Hirst, Juggard and Reeve are incomparably beyond anything that can be found in obstetrical works.—*Journal of the American Medical Association*, September 8, 1888.

In our notice of the "System of Practical Medicine by American Authors," we made the following statement: "It is a work of which the profession in this country can feel proud. Written exclusively by American physicians who are acquainted with all the varieties of climate in the

United States, the character of the soil, the manners and customs of the people, etc., it is peculiarly adapted to the wants of American practitioners of medicine, and it seems to us that every one of them would desire to have it." Every word thus expressed in regard to the "American System of Practical Medicine" is applicable to the "System of Gynecology by American Authors." It, like the other, has been written exclusively by American physicians who are acquainted with all the characteristics of American people, who are well informed in regard to the peculiarities of American women, their manners, customs, modes of living, etc. As every practicing physician is called upon to treat diseases of females, and as they constitute a class to which the family physician must give attention, and cannot pass over to a specialist, we do not know of a work in any department of medicine that we should so strongly recommend medical men generally to purchase.—*Chicagoland Medical News*, July, 1887.

Emmet's Gynecology.—Third Edition.

The Principles and Practice of Gynecology; For the use of Students and Practitioners of Medicine. By THOMAS ADDIS EMMET, M.D., LL.D., Surgeon to the Woman's Hospital, New York, etc. Third edition, thoroughly revised. In one large and very handsome octavo volume of 880 pages, with 150 illustrations. Cloth, \$5.00; leather, \$6.00.

We are in doubt whether to congratulate the author more than the profession upon the appearance of the third edition of this well-known work. Embodying, as it does, the life-long experience of one who has conspicuously distinguished himself as a bold and successful operator, and who has devoted so much attention to the specialty, we feel

sure the profession will not fail to appreciate the privilege thus offered them of perusing the views and practice of the author. His earnestness of purpose and conscientiousness are manifest. He gives not only his individual experience but endeavors to represent the actual state of gynecological science and art.—*British Medical Journal*, May 16, 1888.

Gynecology. Cloth, \$1.00. See *Students' Quiz Series*, page 30.

Tait's Diseases of Women and Abdominal Surgery.

Diseases of Women and Abdominal Surgery. By LAWSON TAIT, F.R.C.S., Professor of Gynecology in Queen's College, Birmingham, late President of the British Gynecological Society, Fellow of the American Gynecological Society. In two octavo volumes. Volume I., 554 pages, 62 engravings and 3 plates. Cloth, \$3.00. Volume II., preparing.

Mr. Tait never writes anything that does not command attention by reason of the originality of his ideas and the clear and forcible manner in which they are expressed. This is eminently true of the present work. Terms of truth are thickly scattered throughout; single happily worded sentences express what another author would have expanded into pages. Useful hints on the technique of surgical operations, ingenious theories on pathology, daring

innovations on long-established rules—these succeed one another with a bewildering rapidity. His position has long been assured; it is hardly possible for him to add to his great reputation as a daring and original surgeon. Few reformers have ever enjoyed the present reward of their labors in such full measure as he. We cannot repress our admiration for the restless genius of the great surgeon.—*American Journal of the Medical Sciences*, June, 1890.

Edis on Diseases of Women.

The Diseases of Women. Including their Pathology, Causation, Symptoms, Diagnosis and Treatment. A Manual for Students and Practitioners. By ARTHUR W. EDIS, M.D., Lond., F.R.C.P., M.R.C.S., Assistant Obstetric Physician to Middlesex Hospital, late Physician to British Lying-in-Hospital. In one octavo volume of 576 pages, with 148 illustrations. Cloth, \$3.00; leather, \$4.00.

The special qualities which are conspicuous are thoroughness in covering the whole ground, clearness of description and conciseness of statement. Another marked feature of the book is the attention paid to the details of many minor surgical operations and procedures, as, for instance, the use of tents, application of leeches, and use of hot-water injections. These are among the more common methods of

treatment, and yet very little is said about them in many of the text-books. The book is one to be warmly recommended, especially to students and general practitioners, who need a concise but complete resume of the whole subject. Specialists, too, will find many useful hints in its pages.—*Boston Medical and Surgical Journal*, March 2, 1892.

HODGE ON DISEASES PECULIAR TO WOMEN Including Displacements of the Uterus. Second edition, revised and enlarged. In one beautifully printed octavo volume of 612 pages, with original illustrations. Cloth, \$4.50.

WEST'S LECTURES ON THE DISEASES OF WOMEN. Third American from the third London edition. In one octavo volume of 543 pages. Cloth, \$3.75; leather, \$4.75.

Lea Brothers & Co., Publishers, 708, 708 & 710 Sansom Street, Philadelphia.

Thomas & Mundé on Diseases of Women.—Sixth Edition.

A Practical Treatise on the Diseases of Women. By T. GAILLARD THOMAS, M.D., LL.D., Emeritus Professor of Diseases of Women in the College of Physicians and Surgeons, New York, and PAUL F. MUNDE, M.D., Professor of Gynecology in the New York Polyclinic. New (sixth) edition, thoroughly revised and rewritten by DR. MUNDE. In one large and handsome octavo volume of 824 pages, with 347 illustrations, of which 201 are new. Cloth, \$5.00; leather, \$6.00.

The profession has sadly felt the want of a text-book on diseases of women, which should be comprehensive and at the same time not diffuse, systematically arranged so as to be easily grasped by the student of limited experience, and which should embrace the wonderful advances which have been made within the last two decades. Thomas' work fulfilled these conditions, and the announcement that a new edition was about to be issued, revised by so competent a writer as Dr. Mundé, was hailed with delight. Dr. Mundé brings to his work a most practical knowledge of the subjects of which he treats and an exceptional acquaintance with the world's literature of this important branch of medicine. The result is what is, perhaps, on the whole, the best practical treatise on the subject in the English language. The original work is preserved as a basis, but amplified and enriched with the results of modern research. Much has been interspersed with the old material and several new chapters added. It is, as we have said, the best text-book we know, and will be of especial value to the general practitioner as well as to the specialist. The illus-

trations are very satisfactory. Many of them are new and are particularly clear and attractive. The book will undoubtedly meet with a favorable reception from the profession.—*Boston Medical and Surgical Journal*, January 14, 1892.

This work, which has already gone through five large editions, and has been translated into French, German, Spanish and Italian, is too well known to require commendation now upon the appearance of this, the sixth edition. It has been thoroughly revised and brought up to date by Dr. Mundé, who is announced as joint author. Many new illustrations have been added, and the text has been increased by the addition of new chapters. The distinctive features of the work, which made it so attractive when first issued, have in a measure been retained, so that it continues to be the most practical and at the same time the most complete treatise upon the subject in print, the changes that have been made only increasing its value.—*The Archives of Gynecology, Obstetrics and Pediatrics*, February, 1891.

Sutton on the Ovaries and Fallopian Tubes.

Surgical Diseases of the Ovaries and Fallopian Tubes, including Tubal Pregnancy. By J. BLAND SUTTON, F.R.C.S., Assistant Surgeon to the Middlesex Hospital, London. In one crown octavo volume of 544 pages, with 119 engravings and 5 colored plates. Cloth, \$3.00.

This is not a book to be read and then shelved; it is one to be studied. It is not based upon hypotheses but upon facts. It makes pathology practical, and inculcates a practice based upon pathology. It is succinct, yet thorough; practical, yet scientific; conservative, yet bold. It is probably on the table of all gynecologists; but it is not for them alone; the general practitioner needs just such a book. It will be of immense service to him in the study of pelvic diseases, and will assuredly open his eyes to the progress made by conscientious, painstaking workers like Dr.

Sutton in the field of pathology and differential diagnosis.—*International Medical Magazine*, September, 1892.

Mr. Sutton has written a book which deserves unstinted praise for the clearness with which it presents the subject and for the originality of the material. No specialist should fail to read it, and it is so written as to be of the greatest service to the general practitioner who wishes to post himself upon the subject of which it treats.—*New York Journal of Gynecology and Obstetrics*, June, 1892.

Davenport's Non-Surgical Gynecology.—Second Edition.

Diseases of Women, a Manual of Non-Surgical Gynecology. Designed especially for the Use of Students and General Practitioners. By FRANCIS H. DAVENPORT, M.D., Assistant in Gynecology in the Medical Department of Harvard University, Boston. Second edition. In one handsome 12mo. volume of 314 pages, with 107 illustrations. Cloth, \$1.75.

The first edition of Dr. Davenport's book, which was published three years ago, evidently met with the reception it deserved, or the second edition would not have followed so soon. The title is an attractive one, and the contents are of value to the student and general practitioner. One advantage of it is that it teaches the physician or the student how to do the little things, or to remedy the minor evils in connection with gynecology. In these days, when major gynecology is so largely practised, minor gynecology is too frequently ignored. To those in the profession who are about to interest themselves particularly in this branch of surgery, and to the student who in the future intends to

make gynecology his life-work, we believe that Davenport's book will be essential to his success, because it will teach him facts which larger works sometimes ignore.—*The Therapeutic Gazette*, October 15, 1892.

Many valuable volumes already exist on the surgical aspects of gynecology, but scant attention has been paid in recent years to the non-surgical treatment of women's diseases. The present volume, dealing with nothing which has not stood the actual test of experience, and being concisely and clearly written, conveys a great amount of information in a convenient space.—*Annals of Gynecology and Pediatrics*, June, 1893.

May's Manual of Diseases of Women.—Second Edition.

A Manual of the Diseases of Women. Being a Concise and Systematic exposition of the Theory and Practice of Gynecology. By CHARLES H. MAY, M.D., late House Surgeon to Mount Sinai Hospital, New York. Second edition, edited by L. S. RAC, M.D., Attending Gynecologist at the Harlem Hospital, New York. In one 12mo. volume of 360 pages, with 31 illustrations. Cloth, \$1.75.

The classification is so clear that the purpose of enabling the student to review the subject, or the practitioner rapidly to refresh his memory, is admirably fulfilled. Taking as authority some of the best systematic writers, and giving in the main an opinion which is a consensus, there is an

absence of personal bias which is not the least valuable point in the work. The book meets its purpose. Whole chapters have been written in other works without expressing more ideas than do pages in this.—*American Journal of the Medical Sciences*, August, 1890.

Duncan on Diseases of Women.

Clinical Lectures on the Diseases of Women; Delivered in St. Bartholomew's Hospital. By J. MATTHEWS DUNCAN, M.D., LL.D., F.R.S.E., etc. In one octavo volume of 175 pages. Cloth, \$1.50.

ASHWELL'S PRACTICAL TREATISE ON THE DISEASES PECULIAR TO WOMEN. Third American from

the third and revised London edition. In one octavo volume of 520 pages. Cloth, \$3.50.

Lea Brothers & Co., Publishers, 706, 708 & 710 Sansom Street, Philadelphia.

Parvin's Art and Science of Obstetrics.—Second Edition.

The Science and Art of Obstetrics. By THEOPHILUS PARVIN, M.D., LL.D., Professor of Obstetrics and the Diseases of Women and Children in Jefferson Medical College, Philadelphia. Second edition. In one handsome octavo volume of 701 pages, with 239 engravings and a colored plate. Cloth, \$4.25; leather, \$5.25.

Through his many able contributions to obstetric literature and by reason of his eminence and popularity as a teacher and practitioner, the author of this volume is well known to the profession of America and obstetricians everywhere. Among his many great efforts this work is his master-piece. He has handled this subject, upon which so much has been written, with an attractiveness that is far from common. The science and art of obstetrics have been well and fully demonstrated. The more difficult and abstruse branches have been accorded deserved attention, while the minutiae, the very little points so important to the practitioner at the bedside, yet so generally ignored by writers, have not been neglected. A number of new cuts have been inserted, and the treatment of every subject is in a manner so clear, so direct, so complete, that little is left to be told and nothing could be told better. The work is therefore, in our estimation, one of the most

valuable and trustworthy to which the obstetrician can appeal.—*Pacific Medical Journal*, November, 1890.

The second edition of this work, following so soon upon its first publication, demonstrates its real value and the favor bestowed upon it by the profession. We regard it as the most valuable text-book for the student of medicine yet published. The author has been a most successful teacher for a long period, and the discipline and training of the lecture room are observed in the clearness with which the often-obscure principles of the science and art of obstetrics are presented to the comprehension of the undergraduate. We think this feature is one of the strongest in the work and commends it especially to teachers. The present edition is greatly improved and embodies all the advances made in this important department of medicine up to the time of its publication.—*Buffalo Medical and Surgical Journal*, December, 1890.

Playfair's Midwifery.—Seventh Edition.

A Treatise on the Science and Practice of Midwifery. By W. S. PLAYFAIR, M.D., F.R.C.P., Professor of Obstetric Medicine in King's College, London. Fifth American from the seventh English edition. Edited, with additions, by ROBERT P. HARRIS, M.D. In one octavo volume of 664 pages, with 207 engravings and 5 plates. Cloth, \$4.00; leather, \$5.00.

Truly a wonderful book: an epitome of all obstetrical knowledge, full, clear and concise. In thirteen years it has reached seven editions. It is perhaps the most popular work of its kind ever presented to the profession. Beginning with the anatomy and physiology of the organs concerned, nothing is left unwritten that the practical accoucheur should know. It seems that every conceivable physiological or pathological condition, from the moment of conception to the time of complete involution, has had

the author's patient attention. The plates and illustrations, carefully studied, will teach the science of midwifery. The reader of this book will have before him the very latest and best of obstetric practice, and also of all the attendant troubles connected therewith.—*Southern Practitioner*, December, 1890.

This work holds a leading place in all medical college catalogues as a standard text-book.—*Columbus Medical Journal*, November, 1889.

King's Manual of Obstetrics.—Fifth Edition.

A Manual of Obstetrics. By A. F. A. KING, M.D., Professor of Obstetrics and Diseases of Women in the Medical Department of the Columbian University, Washington, D.C., and in the University of Vermont, etc. New (fifth) edition. In one 12mo. volume of 446 pages, with 150 illustrations. Cloth, \$2.50.

So comprehensive a treatise could not be brought within the limits of a book of this size were not two things especially true. First, Dr. King is a teacher of many years' experience, and knows just how to present his subjects in a manner for them to be best received; and, secondly, he can put his ideas in a clear and concise form. In other words, he knows how to use the English language. He gives us the plain truth, free from unnecessary ornamentation. Therefore he says there are nine hundred pages of matter between the covers of this manual of four hundred and fifty pages. We cannot imagine a better manual for the hard-worked student, while its clear and practical teachings make it invaluable to the busy practitioner. The illus-

trations add much to the subject matter.—*The National Medical Review*, October, 1892.

This deservedly popular manual has rapidly passed through five editions since its first appearance ten years ago. It is essentially a book for students' use, and is one of the very best of its kind. Its scope in topics is particularly wide, and, though each topic is necessarily treated in a brief manner, it forms an excellent index, so to say, to the complete study of obstetrics. The present edition bears marks of revision, several illustrations having been added and the text amplified.—*The Chicago Medical Review*, October, 1892.

Barnes' System of Obstetric Medicine and Surgery.

A System of Obstetric Medicine and Surgery, Theoretical and Clinical. For the Student and the Practitioner. By ROBERT BARNES, M.D., Physician to the General Lying-in Hospital, London, and FANCOURT BARNES, M.D., Obstetric Physician to St. Thomas' Hospital, London. The Section on Embryology by Professor Milnes Marshall. In one octavo volume of 872 pages with 231 illustrations. Cloth, \$5.00; leather, \$6.00.

The immediate purpose of the work is to furnish a hand-book of obstetric medicine and surgery for the use of the student and practitioner. It is not an exaggeration to say of the book that it is the best treatise in the English language yet published, and this will not be a surprise to those who are acquainted with the work of the elder Barnes. Every practitioner who desires to have the best obstetrical

opinions of the time in a readily accessible and condensed form, ought to own a copy of the book.—*Journal of the American Medical Association*, June 12, 1890.

The authors have made a text-book which is in every way quite worthy to take a place beside the best treatises of the period.—*New York Medical Journal*, July 2, 1887.

Obstetrics. Cloth, \$1.00. See *Students' Quiz Series*, page 30.

Landis on Labor and the Lying-in Period.

The Management of Labor, and of the Lying-in Period. By HENRY G. LANDIS, A.M., M.D., Professor of Obstetrics and the Diseases of Women in Starling Medical College, Columbus, Ohio. In one handsome 12mo. volume of 334 pages, with 28 illustrations. Cloth, \$1.75.

WINCKEL'S COMPLETE TREATISE ON THE PATHOLOGY AND TREATMENT OF CHILDREN. For Students and Practitioners. Translated from the second Ger-

man edition, by J. R. CHADWICK, M.D. In one octavo volume of 484 pages. Cloth, \$4.00.

Lea Brothers & Co., Publishers, 706, 708 & 710 Sansom Street, Philadelphia.

Smith on Diseases of Children.—Seventh Edition.

A Treatise on the Diseases of Infancy and Childhood. By J. LEWIS SMITH, M.D., Clinical Professor of Diseases of Children in the Bellevue Hospital Medical College, New York. Seventh edition, thoroughly revised and rewritten. In one handsome octavo volume of 881 pages, with 51 illustrations. Cloth, \$4.50; leather, \$5.50.

We have always considered Dr. Smith's book as one of the very best on the subject. It has always been practical—a field book, theoretical where theory has been deduced from practical experience. He takes his theory from the bedside and the pathological laboratory. The very practical character of this book has always appealed to us. It is characteristic of Dr. Smith in all his writings to collect whatever recommendations are found in medical literature, and his search has been wide. One seldom fails to find here a practical suggestion after search in other works has been in vain. In the seventh edition we note a variety of changes in accordance with the progress of the times. It still stands foremost as the American text-book. Its advice is always conservative and thorough, and the evidence of research has long since placed its author in the front rank of medical teachers.—*The American Journal of the Medical Sciences*, December, 1891.

In the present edition we notice that many of the chapters have been entirely rewritten. Full notice is taken of

all the recent advances that have been made. Many diseases not previously treated of have received special chapters. The work is a very practical one. Especial care has been taken that the directions for treatment shall be particular and full. In no other work are such careful instructions given in the details of infant hygiene and the artificial feeding of infants.—*Montreal Medical Journal*, February, 1891.

Already in previous editions the treatise of Dr. Smith on Diseases of Children held position undisputed at the head of its class. No book in any language could dispute with it the title to preeminence. A list of works on diseases of children, made up in any country, would have this work at its head, and for the purposes of the great majority of practitioners the list would be complete with this one alone.—*The American Practitioner and News*, May 9, 1891.

As a text-book for students and a guide for young practitioners it is unsurpassed.—*Buffalo Medical and Surgical Journal*, January, 1891.

Diseases of Children. Cloth, \$1.00. See *Students' Quiz Series*, page 30.

Herman's First Lines in Midwifery.

First Lines in Midwifery: a Guide to Attendance on Natural Labor for Medical Students and Midwives. By G. ERNEST HERMAN, M.B., F.R.C.P., Obstetric Physician to the London Hospital. In one 12mo. volume of 198 pages, with 80 illustrations. Cloth, \$1.25. See *Students' Series of Manuals*, page 30.

This little book is intended for the use of midwives and for the guidance of medical students in the care of normal cases. The author is the well-known lecturer on obstetrics to the London Hospital, and he has produced a manual which will prove extremely useful to those for whom it has been prepared. The book is replete with practical advice,

and no student can go wrong who follows its teachings. Much stress has been laid on the now generally approved aseptic management of labor, and it is clearly pointed out in what complications the student should send for assistance. The book is well made and fully illustrated.—*The Boston Medical and Surgical Journal*, February 9, 1893.

Owen on Surgical Diseases of Children.

Surgical Diseases of Children. By EDMUND OWEN, M.B., F.R.C.S., Surgeon to the Children's Hospital, Great Ormond Street, London. In one 12mo. volume of 525 pages, with 4 chromo-lithographic plates and 85 woodcuts. Cloth, \$2.00. See *Series of Clinical Manuals*, page 30.

It would not be easy on any subject to find a more clearly written work, where every word and sentence tells, and from which it seems few could be spared. The work is truly a conspectus of the branch of which it treats, and

covers the field in a way that is done by no other, presenting the gist of what is known of every surgical affection to which childhood and infancy are liable.—*The American Practitioner and News*, November 13, 1886.

Hartshorne's Conspectus of the Medical Sciences.

A Conspectus of the Medical Sciences; Containing Handbooks on Anatomy, Physiology, Chemistry, Materia Medica, Practice of Medicine, Surgery and Obstetrics. By HENRY HARTSHORNE, A.M., M.D., LL.D., lately Professor of Hygiene in the University of Pennsylvania. Second edition, thoroughly revised and greatly improved. In one large royal 12mo. volume of 1023 pages, with 477 illustrations. Cloth, \$4.25; leather, \$5.00.

Ludlow's Manual of Examinations.

A Manual of Examinations upon Anatomy, Physiology, Surgery, Practice of Medicine, Obstetrics, Materia Medica, Chemistry, Pharmacy and Therapeutics. To which is added a Medical Formulary. By J. L. LUDLOW, M.D., Consulting Physician to the Philadelphia Hospital, etc. Third edition, thoroughly revised, and greatly enlarged. In one 12mo. volume of 816 pages, with 370 illustrations. Cloth, \$3.25; leather, \$3.75.

CONDIE'S PRACTICAL TREATISE ON THE DISEASES OF CHILDREN. Sixth edition, revised and augmented. In one octavo volume of 779 pages. Cloth, \$5.25; leather, \$6.25.

LEISHMAN'S SYSTEM OF MIDWIFERY, INCLUDING THE DISEASES OF PREGNANCY AND THE PUERPERAL STATE. Fourth edition. Octavo.

WEST ON SOME DISORDERS OF THE NERVOUS SYSTEM IN CHILDHOOD. In one small 12mo. volume of 127 pages. Cloth, \$1.00.

PARRY ON EXTRA-UTERINE PREGNANCY: Its Clinical History, Diagnosis, Prognosis and Treatment. Octavo, 272 pages. Cloth, \$2.50.

RAMSBOTHAM'S PRINCIPLES AND PRACTICE OF

OBSTETRIC MEDICINE AND SURGERY. In Reference to the Process of Parturition. A new and enlarged edition, thoroughly revised by the author. With additions by W. V. KEATING, M.D., Professor of Obstetrics, etc., in the Jefferson Medical College of Philadelphia. In one large and handsome imperial octavo volume of 640 pages, with 64 full-page plates and 43 woodcuts in the text, containing in all nearly 200 beautiful figures. Strongly bound in leather, with raised bands, \$7.

CHURCHILL ON THE PUERPERAL FEVER AND OTHER DISEASES PECULIAR TO WOMEN. In one octavo volume of 464 pages. Cloth, \$2.50.

TANNER ON PREGNANCY. Octavo, 490 pages, colored plates, 16 cuts. Cloth, \$4.25.

The Students' Quiz Series.

A NEW Series of Manuals, comprising all departments of medical science and practice, and prepared to meet the needs of students and practitioners. Written by prominent medical teachers and specialists in New York, these volumes may be trusted as authoritative and abreast of the day. They enjoy the unique advantage of issue under careful editorial supervision which gives assurance, not only of accuracy, but of the completeness of the Series as a whole, and of the compactness of each volume by the avoidance of duplication. Cast in the form of suggestive questions, and concise and clear answers, the text will impress vividly upon the reader's memory the salient points of his subject, and the prominent and uniform headings will facilitate instant reference to any topic. To the student these volumes will be of the utmost service in preparing for examinations, and they will also be of great use to the practitioner in recalling forgotten details, and in gaining the latest knowledge, whether in theory or in the actual treatment of disease. Nothing has been left undone to make them in type and illustration most attractive and convenient for the eye and mind. Handsomely bound in limp cloth, and in size suitable for the hand and pocket, these volumes are assured of enormous popularity, and are accordingly placed at an exceedingly low price in comparison with their value. For details of subjects and prices see below.

ANATOMY (*Double Number*)—By FRED J. BROCKWAY, M.D., Assistant Demonstrator of Anatomy, College of Physicians and Surgeons, New York, and A. O'MALLEY, M.D., Instructor in Surgery, New York Polyclinic. \$1.75.

PHYSIOLOGY—By F. A. MANNING, M.D., Attending Surgeon, Manhattan Hospital, N. Y. \$1.

CHEMISTRY AND PHYSICS—By JOSEPH STRUTHERS, Ph. B., Columbia College School of Mines, N. Y., and D. W. WARD, Ph. B., Columbia College School of Mines, N. Y., and CHARLES H. WILLMARSH, M.S., N. Y. \$1.

HISTOLOGY, PATHOLOGY AND BACTERIOLOGY—By BENNETT S. BEACH, M.D., Lecturer on Histology, Pathology and Bacteriology, New York Polyclinic. \$1.

MATERIA MEDICA AND THERAPEUTICS—By L. F. WARNER, M.D., Attending Physician, St. Bartholomew's Dispensary, N. Y. \$1.

PRACTICE OF MEDICINE, INCLUDING NERVOUS DISEASES—By EDWIN T. DODGINS, M.D., Member N. Y. Pathological Society, and J. D. SAGEL, M.D., Member N. Y. County Medical Association. \$1.

SURGERY (*Double Number*)—By BERN B. GALLAUDET, M.D., Visiting Surgeon, Bellevue Hospital, New York, and CHARLES DIXON JONES, M.D., Surgeon Yorkville Dispensary, New York. \$1.75.

GENITO-URINARY AND VENEREAL DISEASES—By CHARLES H. CRETWOOD, M.D., Visiting Surgeon, Demilt Dispensary, Department of Surgery and Genito-Urinary Diseases, New York. \$1.

DISEASES OF THE SKIN—By CHARLES C. RANSOM, M.D., Assistant Dermatologist, Vanderbilt Clinic, New York. \$1.

DISEASES OF THE EYE, EAR, THROAT AND NOSE—By FRANK E. MILLER, M.D., Throat Surgeon, Vanderbilt Clinic, New York, and JAMES P. McEVY, M.D., Throat Surgeon, Bellevue Hospital, Out-Patient Department, New York, and J. E. WEEKS, M.D., Lecturer on Ophthalmology and Otolaryngology, Bellevue Hospital Medical College, New York. \$1.

OBSTETRICS—By CHARLES W. HAYT, M.D., House Physician, Nursery and Child's Hospital, New York. \$1.

GYNECOLOGY—By G. W. BRATENHILL, M.D., Assistant in Gynecology, Vanderbilt Clinic, New York, and SINCLAIR TOWNSEY, M.D., Assistant Surgeon, Out-Patient Department, Roosevelt Hospital, New York. \$1.

DISEASES OF CHILDREN—By C. A. RHODES, M.D., Instructor in Diseases of Children, New York Post-Graduate Medical College. \$1.

For special circulars, with full information and specimen pages, address the Publishers.

The *Student's Quiz Series* enables a man in practice to give himself an occasional quiz and see how much he has forgotten. It is intended, however, more particularly for the use of the student, not only to show how much he has yet to learn, but to make its accomplishment easier; to enable him to give his whole attention to lectures on these subjects without note-taking, and to go over in a condensed form, before an examination or quiz, the essential facts pertaining to the special branch.—*Medical Record*, June 3, 1893.

This series of *Quiz-Compenda* is undoubtedly the best that is published. They will repay the practitioner as well as the student for the time spent in a careful study of them, while to the lecturer or author they will very materially

lessen his labors by presenting to him his subject in a brief and classified manner.—*Cincinnati Med. Jour.*, May 15, 1893.

Those who desire to review the salient points of medicine can do so by means of these books in the shortest possible time. The form of question and answer crystallizes the information they contain.—*Brooklyn Med. Jour.*, April, 1893.

Such books serve a useful purpose, not only to the student preparing for examination but to the practitioner, in recalling the more salient characteristics of the affections under consideration.—*Journal of Cutaneous and Genito-Urinary Diseases*, February, 1893.

We know of no series that we would recommend more highly.—*Memphis Medical Monthly*, Feb. 1893.

Student's Series of Manuals.

A Series of Fifteen Manuals, for the use of Students and Practitioners of Medicine and Surgery, written by eminent Teachers or Examiners, and issued in pocket-size 12mo volumes of 300-540 pages, richly illustrated and at a low price. The following volumes are now ready: LUFF'S *Manual of Chemistry*, \$2; HERMAN'S *First Lines in Materia Medica*, \$1.50; TREVIS' *Manual of Surgery*, by various writers, in three volumes, per set, \$6; BELLI'S *Comparative Anatomy and Physiology*, \$2; GOULI'S *Surgical Diagnosis*, \$2; ROBERTSON'S *Physiological Physics*, \$2; BRUCE'S *Materia Medica and Therapeutics* (fifth edition), \$1.50; POWER'S *Human Physiology* (second edition), \$1.50; CLARKE and LEWIS' *Illustrated Manual*, \$1.50; KALPE'S *Clinical Chemistry*, \$1.50; TREVIS' *Surgical Applied Anatomy*, \$2; PEPPEY'S *Surgical Pathology*, \$2; and KLEIN'S *Elements of Histology* (fourth edition), \$1.75. The following is in press: PEPPEY'S *Forensic Medicine*. For separate notices see index on last page.

Series of Clinical Manuals.

In arranging for this Series it has been the design of the publishers to provide the profession with a collection of authoritative monographs on important clinical subjects in a cheap and portable form. The volumes contain about six pages and are freely illustrated by chromo-lithographs and woodcuts. The following volumes are now ready: YAM on *Food in Health and Disease*, \$2; BRIDGHENT on *The Pulse*, \$1.75; CARTER & FROST'S *Ophthalmic Surgery*, \$2.50; HERRICK on *Syphilis*, \$2.50; MARSH on *The Joints*, \$2; OWEN on *Surgical Diseases of Children*, \$2; MORRIS on *Surgical Diseases of the Kidney*, \$2.50; PICK on *Fractures and Dislocations*, \$2; RUTLIN on *The Tongue*, \$2.50; TREVIS on *Intestinal Obstruction*, \$2; and SAVAGE on *Insanity and Allied Nervoses*, \$2. The following is in preparation: LUCAS on *Diseases of the Urethra*. For separate notices see index on last page.

Lea Brothers & Co., Publishers, 706, 708 & 710 Sansom Street, Philadelphia.

Taylor's Medical Jurisprudence.—New Edition. Just Ready.

A Manual of Medical Jurisprudence. By ALFRED S. TAYLOR, M.D., Lecturer on Medical Jurisprudence and Chemistry in Guy's Hospital, London. New American from the twelfth English edition. Thoroughly revised by CLARK BELL, Esq., of the New York Bar. In one octavo volume of 787 pages, with 56 illustrations. Cloth, \$4.50; leather, \$5.50.

This is a complete revision of all former American and English editions of this standard book. This edition contains a large amount of entirely new matter, many portions of the book having been rewritten by the editor. Many cases and authorities have been cited, and the citations brought down to the latest date. The book has so long been a standard treatise on the subject of medical jurisprudence, and has gone through so many editions—twelve English and eleven American—that there is little left to criticize, unless it is to note the admirable manner in which Mr. Clark Bell, in editing this edition, has enlarged and improved what already seemed complete, by bringing his many citations of cases down to date to meet the present law; and by adding much new matter he has furnished the medical profession and the bar with a valuable book of reference, one to be relied upon in daily practice, and quite up to the present needs, owing to its exhaustive character. It would seem that the book is indispensable to the library of both physician and lawyer, and particularly the legal practitioner whose duties take him into the criminal courts. Too much praise cannot be given to the editor for his thor-

ough and painstaking labors, by which he has given to two professions a reference-book to be relied upon.—*The American Journal of the Medical Sciences*, April, 1893.

No library is complete without Taylor's *Medical Jurisprudence*, as its authority is accepted and unquestioned by the courts.—*Buffalo Medical and Surgical Journal*, June, 1893.

There is no other work upon the subject which has been so uniformly recognized or so widely quoted and followed by courts in England and this country. It would have been impossible to select anyone in this country better fitted for the task of revision than Mr. Bell. Profiting by the labors with which Dr. Stevenson has enriched the twelfth English edition, he has, in this eleventh American edition, given us a book fully abreast with the most recent thought and knowledge. On the basis of his own researches, of the investigations of scientists throughout the world, and of the decisions of our own courts, he has incorporated in it a wealth of practical suggestion and instructive illustration which cannot fail to strengthen the hold it has so long had upon the profession.—*The Criminal Law Magazine and Reporter*, January, 1893.

BY THE SAME AUTHOR.

Poisons in Relation to Medical Jurisprudence and Medicine. Third American, from the third and revised English edition. In one large octavo volume of 788 pages. Cloth, \$5.50; leather, \$6.50.

Lea's Superstition and Force.—New Edition. Just Ready.

Superstition and Force: Essays on the Wager of Law, The Wager of Battle, The Ordeal and Torture. By HENRY CHARLES LEA, LL.D. New (fourth) edition, revised and enlarged. Royal 12mo., 629 pages. Cloth, \$2.75.

Both abroad and at home the work has been accepted as a standard authority, and the author has endeavored, by a complete revision and considerable additions, to render it more worthy of the universal favor which has carried it to a fourth edition. The style is severe and simple, and yet dignified with its elegance and reserved strength. The known erudition and fidelity of the author are guarantees that all possible original sources of information have been

not only consulted but exhausted. The subject matter is handled in such an able and philosophic manner that to read and study it is a step toward liberal education. It is a comfort to read a book that is so thorough, well conceived and well done. We should like to see it made a text-book in our law schools and prescribed course for admission to the bar.—*Legal Intelligencer*, March 3, 1893.

BY THE SAME AUTHOR.

Chapters from the Religious History of Spain. In one 12mo. volume of 522 pages. Cloth, \$2.50.

The width, depth and thoroughness of research which have earned Dr. Lea a high European place as the ablest historian the Inquisition has yet found are here applied to some side-issues of that great subject. We have only to say of this volume that it worthily complements the author's

earlier studies in ecclesiastical history. His extensive and minute learning, much of it from meditated manuscripts in Mexico, appears on every page.—*London Antiquary*, January, 1891.

The Formulary of the Papal Penitentiary. In one octavo volume of 221 pages, with a frontispiece. Cloth, \$2.50. *Just ready.*

The text is edited with the care and learning which we should have expected of the historian of the "Inquisition of the Middle Ages," and is illustrated with valuable notes and an introduction of remarkable interest. If his

judgment of the whole system is a hard one it is to be remembered that he is here in accord with a succession of the greatest religious teachers of the medieval church.—*English Historical Review*, July, 1893.

Studies in Church History. The Rise of the Temporal Power—Benefit of Clergy—Excommunication—The Early Church and Slavery. Second and revised edition. In one royal octavo volume of 605 pages. Cloth, \$2.50.

The author is preeminently a scholar; he takes up every topic allied with the leading theme and traces it out to the minutest detail with a wealth of knowledge and impartiality of treatment that compel admiration. The amount of information compressed into the book is extraordinary, and the profuse citation of authorities and references makes

the work particularly valuable to the student who desires an exhaustive review from original sources. In no other single volume is the development of the primitive church traced with so much clearness and with so definite a perception of complex or conflicting forces.—*Boston Traveller*.

An Historical Sketch of Sacerdotal Celibacy in the Christian Church. Second edition, enlarged. In one octavo volume of 685 pages. Cloth, \$4.50.

This subject has recently been treated with very great learning and with admirable impartiality by an American author, Mr. Henry C. Lea, in his *History of Sacerdotal Celibacy*, which is certainly one of the most valuable works that America has produced. Since the great history of Dean Milman, I know no work in English which has thrown

more light on the moral condition of the Middle Ages, and none which is more fitted to dispel the gross illusions concerning that period which positive writers and writers of a certain ecclesiastical school have conspired to sustain.—*Lecky's History of European Morals*, Chapter V.
